ANEMIA OF PREGNANCY

RELATION TO ANEMIA IN GENERAL

V C ROWLAND, M D

CLEVELAND

The specificity of liver extract in the pernicious or hyperchromic anemia of pregnancy and of large doses of iron in the secondary or hypochromic type of anemia of pregnancy has greatly increased the interest in this subject and in the deficiency factors in anemia in general.

The high incidence of some degree of anemia in pregnancy, when looked for, and the demonstration of deficiency factors in its etiology also establish the great preventive opportunity in prenatal and health supervision work. It has been stated that, next to the blood and blood pressure, a blood count is of the greatest importance during pregnancy. The pernicious form of anemia, untreated, has had a 65 per cent mortality. None of 500 cases on record had prenatal care been given. The secondary form of pregnancy anemia, by overcoming of resistance, may dispose to a variety of obstetric complications and infections.

THE PERNICIOUS OR HYPERCHROMIC FORM

The pernicious form, though rather rare in general, occurred in six of our twenty-eight cases and approximately in the same proportion, namely, one sixth, of Mot's cases of high grade anemia of pregnancy (45 per cent hemoglobin or less). The clinical picture of this condition may be characterized as follows.¹ An insidious onset of anemia in the latter months of pregnancy sometimes not recognized till in the puerperium. Usually, however, there are symptoms of postpartum weakness, breathlessness on exertion, palpitation, headaches, dizziness, some edema of the feet, and occasionally an associated definite toxemia of pregnancy with albuminuria and hypertension. On account of the toxemia, the anemia may be overlooked if the blood is not examined. Labor may come on prematurely, it is characteristically short and relatively painless. Postpartum bleeding is scant. Stillbirth may occur, but a living child does not share in the anemia and develops normally. Labor aggravates the anemia. The patient may go into collapse during delivery or shortly thereafter if the anemia is quite marked. After parturition convalescence usually starts promptly, but there may be rapid progression in the anemia in the first week or two following delivery. At times this course is quite slow so that a serious degree of anemia is recognized only after a month or more of supposedly simple delay in convalescence and returning strength.

Hematologically the pernicious anemia of pregnancy is a hyperchromic macrocytic type quite similar to or

identical with Addisonian anemia. Apparently the same etiologic mechanisms hold for the two conditions, and like therapy is equally efficacious. Castle has shown in the pregnancy cases as in ordinary pernicious anemia that beefsteak alone has no effect on blood formation, but the product of beefsteak and normal human gastric juice produces a specific response like that of liver. Since pregnancy anemias do not relapse, it may be concluded that the anemia is due to the temporary loss of the intrinsic factor in gastric digestion during pregnancy, with a return to normal after that metabolic load has been removed. There is a relative deficiency of this specific intrinsic factor during gestation quite comparable to the relative pancreatic deficiency in the pregnancy glycosuria which clears up after delivery.

THE SECONDARY OR HYPOCHROMIC FORM

The secondary or hypochromic type of anemia is very common in mild degree and, much more frequently than is generally appreciated, reaches a serious degree. Castle and Strauss² studied a group of normal pregnant women by observing the blood, the gastric juice and the dietary history. More than half of these women showed a marked hypochlorhydria during pregnancy, with a return to normal following delivery. There was a 12 per cent average hemoglobin loss during pregnancy in these cases as against a 5 per cent average loss in those with normal gastric contents and diets. Three women with permanent posthistanine gastric achlorhydria had an 18 per cent average hemoglobin loss in spite of normal diet. Nineteen out of thirty-five women with less than 45 per cent hemoglobin during the latter half of pregnancy were found to have posthistanine gastric achlorhydria and twelve more had little or no free hydrochloric acid following alcohol test meals, showing the relationship between gastric digestion and the anemia. These women were found to have been taking a diet definitely deficient in iron, mineral elements and protein. Liver extract produced no improvement in these secondary cases, but all improved rapidly with large doses of iron whether treated during or after pregnancy.

The observations in the secondary or hypochromic type of pregnancy anemia correspond to those of similar studies on certain simple secondary anemias and indicate that the etiologic factors of dietary deficiencies and deficiencies in gastric digestion associated with achlorhydria or hypochlorhydria are common to the two. Apparently the blood requirements of the fetus correspond to blood loss or other causes of secondary anemia in throwing a metabolic overload on the function of hematogenesis during pregnancy. Moreover, the response to iron is as great in the hypochromic anemia of pregnancy as in other hypochromic anemias. A

reticulocyte response may be observed with adequate dosage, but it is not as marked as in the hyperchromic anemia treated with liver

BLOOD IN MOTHER AND INFANT

Incompatibility of blood grouping between the mother and the infant was reported a few years ago as the basis of the anemia of pregnancy, but this was soon found to be not generally true. Galloway³ in 1929 reported that of eighty-four pairs of mothers and infants, fifty-three pairs were in unlike groups. The mothers of like infants averaged 63 per cent hemoglobin and 3,730,000 red blood count, and those unlike infants averaged 67 per cent hemoglobin and 3,830,000 red blood count. In eleven severe cases with hemoglobins of from 40 to 60 per cent, at term there were nine in which mother and infant were compatible. Obviously, the matter of blood grouping is quite independent of the nutritional factor that disturbs hematogenesis during pregnancy.

The infant does not share in the anemia of the mother whether or not their blood happens to fall in the same group. A highly anemic mother may and usually does bear a child with a normal blood. Conversely, rare cases of high grade anemia in new-born infants are found with mothers having a normal blood count.

Hematogenesis seems to be independent but similar in mother and child. The anemias of early infancy respond to liver extract and iron, as recently reported by Maurer, Greengard and Kluver.⁴ Williamson found that normal infants on a milk diet lose in the hemoglobin content of their blood from 23.5 Gm per hundred cubic centimeters at birth to about 13 Gm at 4 months. The rate of this decline depends on the infant's nutrition, and the decline is promptly checked by liver extract and iron.

MATERNAL ANEMIAS

In our series of twenty-eight cases of pregnancy anemia, six were found to be of the primary or hyperchromic type, as indicated by poikilocytosis, macrocytosis and high color index. Some of these cases were seen before the period in which liver treatment was used. Undoubtedly during this period there were many milder cases of the secondary type unrecognized. Some of the severer cases regarded as secondary showed evidences, such as moderate poikilocytosis and anisocytosis, of a mixture of primary and secondary factors. As Minot has pointed out, in Addisonian anemia there may remain, after adequate treatment with liver extract, a simple hypochromic anemia requiring massive doses of iron and a balanced diet to restore the blood to full normal. In my series there were a number of complications or associated conditions, such as pernicious vomiting, psychoses, marked gastro-intestinal disturbances, yet up to the present time no real attempt has been made to carry out a rational prophylaxis in these cases.

The following case report of a pernicious or hyperchromic anemia of pregnancy is given to illustrate the failure of response to iron and ammonium citrate and the specificity of response to desiccated hog stomach during the latter months of pregnancy in spite of a chronic infection.

Mrs. T. M., aged 22, a secundipara, came from Italy during an early pregnancy. She was first seen, Aug. 28, 1930, at about the seventh month of pregnancy, with a transient fever probably

associated with an old rheumatic mitral and aortic endocarditis. By September 6 the temperature and pulse became normal and stayed normal. August 28, the red blood count was 2,310,000, hemoglobin, 50 per cent, white blood count, 9,700. Iron and ammonium citrate, 60 grains (4 Gm.) a day, was started. September 19, the red blood count was 1,970,000, progressing by September 24 to 1,750,000, hemoglobin 50 per cent, white blood count, 5,000. The anemia was of the primary type with a color index of 1.4 poikilocytosis and macrocytosis. After this progressive increase in the anemia from September 6 to 24, in spite of a normal temperature and general comfortable condition and iron, the latter was stopped and desiccated hog stomach started—two vials a day, September 25. The following striking response was noted:

Sept. 24, 1930, red blood cells, 1,750,000, hemoglobin, 50 per cent

October 7, red blood cells, 2,100,000, hemoglobin, 50 per cent

October 22, red blood cells, 2,200,000, hemoglobin, 53 per cent

November 1, red blood cells, 2,330,000, hemoglobin, 58 per cent

November 7, red blood cells, 3,100,000, hemoglobin, 60 per cent

November 10, red blood cells, 3,430,000, hemoglobin, 60 per cent

November 11 (delivery), red blood cells, 3,000,000

Sept. 16, 1932, red blood cells, 5,120,000, hemoglobin, 87 per cent

After parturition there was the usual recession in the red blood count followed by rapid improvement. A doubling of the red blood count during the last six weeks of pregnancy was in contrast to a rapid increase in anemia on iron before the use of desiccated hog stomach. The patient's general condition remained good.

An extensive study of the anemia of pregnancy was made by Wills⁵ in India, where the disease is widely prevalent and related to dietary habits. Women by and large who are well fed are not anemic. The hospital classes, who are both quantitatively and qualitatively ill fed, presented a chronic so-called Bombay anemia. In one study of these cases the average daily protein intake was only 8 Gm. There were other factors, however, since there was a high incidence of pregnancy anemias among Mohammedan women who are meat eaters. In the anemic group there was a deficiency in (1) calories, (2) both animal protein and fat, (3) fresh fruit and vegetables and therefore (4) vitamins A, B and C, and (5) salts. The diets of mothers of premature infants were often deficient in vitamin B.

OTHER DEFICIENCY ANEMIAS

There is also a deficiency anemia in India known as tropical macrocytic anemia and, except for the accident of pregnancy, it is indistinguishable from the pernicious form of pregnancy anemia. This tropical macrocytic anemia occurs alone, with pregnancy, or complicated with malaria, hookworm disease and sprue. The response to treatment is very instructive. Iron and arsenic, in whatever form, are useless, according to all workers in India who recognize this form of anemia. Liver is specific and produces a typical reticulocyte response. In desperate cases with less than 20 per cent hemoglobin, if the patients survive the first five days they are restored to life and health with large doses of liver extract. Before this response, death may occur from acute heart failure. In pregnant patients after delivery there may be a natural remission just as in patients in America who survive the exacerbation due to the strain of labor.

Studies in Pernicious Anemia of Pregnancy. A Survey of Dietetic and Hygienic Conditions of Women in Bombay, *ibid.* 18: 283 (July) 1930.

Curiously, in India the cases responded also to vitamin B preparations. A series of twenty-two cases treated with an autolyzed yeast preparation in drachm (4 Gm) doses, from two to four times a day, showed a response quite comparable to that of liver extract. This response was obtained even in the presence of untreated malaria or hookworm infestation and is quite in contrast with its complete inactivity in the secondary anemia that so frequently accompanies these infections without the nutritional fault. The macrocytic anemia represents a dietetic deficiency disease. In addition to its vitamin B content, the protein of the autolyzed yeast preparation is known to be of good biologic value. In any event, the autolyzed yeast preparation, although of vegetable origin, has an effect identical with liver extract, with a specific reticulocyte response. The effect of both is inhibited by septic infections, so that large doses are required just as with liver extract in pernicious anemia.

Studies of the anemia of sprue by Castle and Rhoads⁶ showed precisely the same mechanism in this nutritional disease, which has an achlorhydria in about half the cases. The deficient substance is apparently identical with that produced by beef muscle and normal gastric juice. Liver extract either by mouth or by injection produced prompt relief from the sore tongue and diarrhea of sprue. The characteristic reticulocyte crisis was obtained, though sometimes atypical. In many cases there is an associated hypochromic or secondary type of anemia in which iron and ammonium citrate is specific. In a few cases, also, autolyzed yeast preparations produced reticulocyte crises and improvement of blood. No relation to the presence or absence of *Monilia psilosis* was found. In the hyperchromic cases, bone marrow biopsies resembled closely those of pernicious anemia.

Even in hookworm anemia, as studied by Castle and Rhoads in Puerto Rico, dietary deficiency and gastrointestinal changes were found to be of major etiologic significance, since a much greater immediate response was obtained by treatment with iron and ammonium citrate in the presence of the parasites than by the elimination of hookworms without such treatment.

In bothriocephalus anemia, which occurs in approximately 1 in 5,000 people infested with the fish tapeworm, it was recognized long ago by Schauman⁷ that there are other basic etiologic factors than the parasite. Remissions of the anemia were observed without expulsion of the worm and with fatal recurrences as in ordinary pernicious anemia. Seventeen cases were recorded with cure by vermifuges, in which death later occurred from pernicious anemia without the presence of the worm. There seems also to be a family and racial predisposition to the anemia. Hypochlorhydria occurs in about 83 per cent of cases. There have been a few observations of cord lesions resembling the subacute combined sclerosis. There are cases with long standing bothriocephalus infestation in which anemia develops only with the added burden of pregnancy. Schauman had five cases in which the anemia started during pregnancy or during the puerperium, representing 20 per cent of his twenty-six female cases. Bothriocephalus anemia, like the other macrocytic anemias, responds promptly to liver treatment in characteristic fashion. There is a spontaneous reticulocytosis following the

expulsion of the parasite just as there is after parturition in the pregnancy cases. However, this is much slower and often incomplete. Here again liver treatment promptly restores the blood to normal. Even in the presence of the fish tapeworm, the anemia responds to liver treatment just as hyperchromic anemia responds during pregnancy. Obviously there is a basic deficiency in all these anemias that is not brought out under ordinary conditions of living. Under various conditions of strain, certain individuals are unable to maintain, at least in relation to their blood-forming organs, the so-called biologic equilibrium.

The results obtained in studies of widely different groups of anemia, with pregnancy and without, have advanced the knowledge of the physiology of hematogenesis in general. There is evidence, especially in the pregnancy cases, of direct dietetic deficiencies or nutritional deficiencies associated with gastric achlorhydria interfering with the production and absorption of those specific substances which excite reticulocytosis and blood formation.

PRACTICAL MANAGEMENT

Intelligent management of pregnancy must include a check up on the condition of the blood, and, when there is any degree of anemia, a supervision of diet, the administration of iron in the secondary or hypochromic form, and the use of liver extract promptly on the appearance of evidence of the rarer pernicious form or in pregnancy anemia, which is refractory to treatment by iron. These anemias of pregnancy and the associated nutritional deficiency may be at least one of the etiologic factors in pernicious vomiting, premature birth, dental caries, thyroid enlargement, faulty lactation, delayed involution, postpartum psychoses and lowered resistance to tuberculosis and other infections. The relation of hypothyroid function to pregnancy anemia also needs to be studied.

The important thing is for the physicians to be sensitized to the possibility, during pregnancy, of overstrain on the function of hematogenesis, which occurs very commonly in slight degree and occasionally in a serious degree. If iron is needed, it should be used in the massive doses of from 90 to 120 grains (6 to 8 Gm) a day in order to get the specific response. A 50 per cent solution of iron and ammonium citrate in drachm doses is very well borne if taken in fruit juice or broth through a tube. Liver extract and iron may be used simultaneously, when there is a suggestion of the hyperchromic form of anemia. Although usually distinct, there seem to be some mixed forms. The history of the tendency to anemia either in the patient or in her family is of definite significance and doubly so during pregnancy. It is not uncommon in pernicious anemia to get the history of a lifelong tendency to simple anemia in the patient or in various members of the family for many years before the onset of the pernicious form and during remissions of the disease.

Prenatal supervision should prevent high grade anemia of pregnancy. Transfusion should not be necessary except in an emergency, when it may be a life saving measure. Many transfusions have been done during pregnancy without complications. In severe cases one may take advantage of the prompt response to liver extract by intravenous injection, although the intramuscular injection is almost as prompt and probably safer. The reticulocyte response occurs in from twenty-four to thirty-six hours. If the patient can be tucked over the first five day period, blood regeneration

⁷ Schauman, Ossian. Zur Kenntnis der sogenannten Bothriocephalus Anämie. *Heimische Medizin* und *Goos* 1899.

or sore tongue with "acid" fruits and the like, and a history of several relapses and remissions of pallor and weakness. These patients can only rarely date the onset of their pallor but have been "pale for years" or ever since they can remember. Relapses in these cases may often be associated with pregnancy—nine times in the present series. Disorders of menstruation are common and may be manifested as menorrhagia or diminished menses. Paresthesias of the fingers and toes are at times complained of, and in one case there was a history of ataxia. On direct questioning, a history of brittle finger nails and of early graying of the hair is frequently obtained. Nervousness and a worrisome temperament are almost invariably present. There is usually a history of marked loss of weight.

The symptoms are characteristically chronic in nature, the patients having usually consulted numerous physicians and having frequently been given pills of ferrous carbonate. The symptomatology, it must be admitted, is usually so vague that the diagnosis of a definite disease entity is not ordinarily made. Particular attention should be paid, however, to a long history of pallor and to such special features as peculiar dietary, burning tongue, brittle finger nails and early graying of the hair. A history of familial anemia may sometimes be obtained.

SIGNS

Physical examination reveals a varying degree of pallor, which is "white" or "straight", i e., without jaundice. At first glance, the skin may appear to be yellowish, but this coloration is due not to jaundice but to the "unmasking" by the lack of hemoglobin of the underlying yellow of the skin. The skin takes on another characteristic feature, which has been stressed by Davies,³ i e., it becomes very wrinkled. Even the younger women with the disease have the atrophied, inelastic, wrinkled skin ordinarily seen only in the aged

Coarse wrinkles about the mouth are common and at times excoriations are seen. The hair is dry and inelastic. Graying of the hair is common and often pronounced. The "pepper and salt" appearance to the hair so often seen in pernicious anemia is also common here. This is frequently a familial characteristic. Great interest must center in the appearance of the tongue, which almost without exception is abnormal. Its exact condition varies with the duration of the disease and the severity of the symptoms. In the early

cases, it is intensely red and has the appearance of inflammation, the papillae cannot be seen, the normal coat is absent. In a long standing case, the tongue is characteristically much smaller than normal, definitely atrophied, very shiny, and completely devoid of coat and papillae. Davies³ aptly calls it "bald." Other cases may show a combination of these two types of

25	M L	Absent	Absent	Low	—	—

signs. At times, only small areas of redness, usually at the tip, are present. The abdominal wall is flabby. The spleen is not usually palpable. The appearance of the nails is often striking and has been stressed by Kaznelson⁵ and Davies⁸. There is often a complaint of brittle nails, which on examination are found flattened, in some cases actually concave or "spooned." They are usually smaller than normal, lack the normal luster, and frequently present vertical ridges.

THE BLOOD

There is a marked reduction in hemoglobin together with only a slight or moderate reduction in the red blood cell count. The color index is thus markedly reduced and, as a corollary, the red blood cells show marked hypochromia (achromia). The erythrocytes are also markedly reduced in size (microcytosis), the average red blood cell diameter being usually well below 7 microns. The lowest hemoglobin reading in the series was 12 per cent (case 1), the lowest erythrocyte count, in the same case, 1.8 millions, and the lowest average red blood cell diameter, 6.02 microns. Normoblasts are rarely seen. Reticulocytes are present in normal or diminished percentages and the blood platelets are usually moderately diminished. In case 2 the latter elements were so reduced (44,000 per cubic millimeter) that petechial hemorrhages and ecchymoses were present. The white blood cells are also usually reduced, leukopenia being present in almost every case. Counts of from 4,000 to 6,000 per cubic millimeter are common, and occasionally counts of from 2,000 to 3,000 are seen.

THE GASTRIC SECRETION

The best studies are those of Davies¹⁰. He has noted, as have all who have written on the subject, the almost constant presence of achlorhydria, but in addi-

10 Davies D T. Studies on Achlorhydria and Anemia. Quart J Med 24: 447 (July) 1931.

tion he has emphasized the low volumes, the presence of an increased amount of mucus, and the marked diminution in pepsin content. He also points out the rapid emptying time of the stomach. Davies examined twenty-four cases following the injection of histamine and found that sixteen showed a secretion of free hydrochloric acid after this procedure. Of the present series of twenty-five cases, free hydrochloric acid was absent in twenty-three instances (table 3) with the ordinary test meal, the other two cases showing traces of free acid. Seventeen patients with achlorhydria were then given histamine, which in fourteen failed to produce a secretion of free hydrochloric acid. In every case, the volumes of gastric juice were low, often only a few cubic centimeters, and the presence of thick mucus often made aspiration difficult.

Castle¹¹ has demonstrated, in the study of a few cases of primary hypochromic anemia, that the "λ" factor, which is lacking from the gastric secretion of patients with pernicious anemia, is present in this disease. In a previous publication, I⁶ have postulated that the achlorhydria of primary hypochromic anemia might be evidence of a gastric juice which is defective in the digestion of iron-containing food, resulting thus in an iron deficiency in the body. I have attempted to confirm this in one case by following Castle's technic for demonstrating the presence or absence of the "λ" factor in gastric juice.

CASE 9¹²—E. A., a woman, aged 50, had complete achlorhydria and marked hypochromic anemia. Large amounts of iron-containing foods, one-half pound (225 Gm.) of spinach and yolks of four eggs were given daily. There was no increase in reticulocytes, hemoglobin or erythrocyte count (fig 1). She was thereupon given by stomach tube a mixture of normal gastric juice which had been incubated for one hour at 37.5 C with one-half pound of finely cut spinach and the yolks of four

Fig 1—The effect of feeding (a) the yolks of six eggs and 225 Gm. of spinach daily and (b) the same foods incubated for two hours with normal gastric juice. There are definite reticulocyte and erythrocyte responses but there is only a slight increase in hemoglobin percentage.

eggs. On the sixth day of this treatment there was a slight rise in reticulocytes, which reached a peak of 85 per cent on the ninth day. Following this rise, there was slight increase in hemoglobin (from 30 to 35 per cent) and rather marked increase in erythrocyte count (from 3.1 millions to 4.8 millions on the twenty-first day). None of these increases were per-

manent, however, since there was prompt relapse even before treatment was discontinued. Later observations showed prompt response to inorganic iron.

This single observation is, to be sure, of but little value, although it points in the direction that the gastric juice of a patient with primary hypochromic anemia may be defective in the digestion of organic iron. Further observations along this line are indicated.

Fig 2—The effect in case 9 of giving (a) desiccated hog stomach (b) iron and ammonium citrate 3 Gm daily (c) iron and ammonium citrate 6 Gm daily (d) the same medication with added copper sulphate (e) omitting medication. There is a slight reticulocyte response with desiccated hog stomach but no definite effect on hemoglobin or erythrocyte production. The effect of iron and ammonium citrate, 3 Gm daily, is striking but at the end of one month, both hemoglobin and erythrocyte counts remain practically stationary. This is remedied strikingly by added copper. When copper is discontinued there is again a relapse which is continued when all medication is omitted.

In four cases, the gastric juice was studied from three months to one year after the blood had become normal (cases 1, 6, 8 and 9). These patients all showed complete achlorhydria before treatment. There was no change in this condition after treatment. The same has been found to hold true in cases of pernicious anemia after treatment with liver extract.

OTHER LABORATORY DATA

The icteric index is low (from 4 to 6) and the bilirubin content of the blood serum is diminished. Diminution in bilirubin is probably due to the normal degree of blood destruction in the presence of diminished hemoglobin and erythrocyte values. The condition of the bone marrow has been presented in a previous publication.⁸ Biopsy of the sternal bone marrow shows, even in the presence of marked anemia, marked hyperplasia of the red cell forming elements. The hyperplasia is of the normal nucleated red cells (erythroblasts and normoblasts) and not of the primitive or embryonic megaloblasts seen in pernicious anemia.

SPECIAL FEATURES AND CONTRIBUTORY FACTORS

The characteristic features in the disease may be summarized as follows:

(a) *Symptoms*—Chronic weakness, dyspnea, gastro-intestinal disturbances, sore tongue, with tendency to remissions and relapses.

(b) *Signs*—Pallor, glossitis, dry, graying hair, brittle, often "spooned" finger nails.

(c) *Laboratory Observations*—Anemia of low color index, achlorhydria, hyperplasia of erythroblasts in the marrow.

12. From the Research Division of the Boston State Hospital. I am indebted to Dr. James A. May for permission to use this case.

The various causes for secondary anemia are not usually present. Careful search in these cases was always made for hemorrhage, particularly from the bowel, as well as for infection, for a malignant condition and for poisons such as lead. It is true that in two of these cases (1 and 18) a certain degree of menorrhagia was present, in case 7 there was a slight chronic loss of blood from hemorrhoids. However, it did not seem possible that the anemia, together with the accompanying clinical picture, could be secondary merely to the loss of blood, since (1) the loss of blood was usually slight (cases with marked menorrhagia were excluded) and (2) the same or greater loss of blood in many other patients was certainly not productive of the same degree of anemia or the same clinical picture. It is, to be sure, possible that the anemia was intensified by the loss of blood.

Analysis of the present series of twenty-five cases resulted in the formation of two groups: (1) fourteen cases that were completely idiopathic and (2) eleven cases in which an associated condition or disease was present. In the latter group, recent pregnancy was a factor in six cases, dysphagia (the Plummer-Vinson syndrome) was present in one case, myxedema and beef tapeworm were factors in other single cases, and operations on the stomach had been performed in two other cases. These conditions did not in themselves appear sufficient to bring about the syndrome delineated, but they undoubtedly increased the necessity for blood formation. The anemia in this group appeared to be due to a summation of several factors, chief among which was probably an inherent abnormality in blood formation, which in turn might be dependent on a poorly functioning gastro-intestinal tract.

A. THE ORDINARY, TYPICAL OR IDIOPATHIC GROUP

There were fourteen cases in the idiopathic group. Two of these may be cited as examples.

CASE 1¹³—H. H., a woman, aged 44, had dyspnea, weakness, loss of weight, diarrhea and marked pallor in 1925 (relapse 1). There was prompt response to the use of iron pills. Relapse 2 took place in 1926 with a recurrence of the symptoms, which again responded to iron pills. Relapse 3 took place in 1928, she was taking no iron pills and became progressively weaker. She had marked diarrhea and lost considerable weight. Marked soreness of the tongue and paresthesias of the fingers and toes developed. By July, 1930, she could hardly walk about and had lost 30 pounds (14 Kg.). On admission to the hospital she showed profound anemia (hemoglobin, 12 per cent, red blood cell count, 1,960,000), leukopenia (3,700 white blood cells per cubic millimeter) and thrombocytopenia. The erythrocytes were hypochromic and much smaller than normal. The tongue was glossy and atrophied. The finger nails were "spooned." The signs of combined system disease were present. There was complete achlorhydria. The bone marrow showed marked hyperplasia of normoblasts and erythroblasts. No response occurred with liver extract, but with large doses of iron and ammonium citrate there was prompt response in reticulocytes, hemoglobin and red blood cell counts. The appetite became voracious. In three months, hemoglobin was 88 per cent, the erythrocyte count was almost 50 million per cubic millimeter and the patient had gained 40 pounds (18 Kg.). The tongue had become normal. She disappeared from observation from November, 1930, to February, 1932, and had discontinued iron medication on the former date. Relapse 4 began in March, 1931, but was terminated quickly when she took the remainder of her iron medication. Relapse 5 began in November, 1931, and in February, 1932, she returned to the clinic with hemoglobin 30 per cent and the erythrocyte count 248 millions. There was again prompt response to iron medication.

CASE 12—Jennie C., a woman, aged 40, began to have, one year prior to admission, precordial pain on exertion. She became very weak and lost her appetite, pallor developed and she was unable to sleep well. Examination disclosed a markedly wrinkled face, excoriations about the mouth, moderate pallor, dry hair, an atrophied glossy tongue, spooned finger nails, complete achlorhydria and marked hypochromic anemia (hemoglobin 30 per cent, erythrocyte count 297 millions). There was a prompt response to large doses—from 4 to 6 Gm. (60 to 90 grams) daily—of reduced iron, the hemoglobin rising to 86 per cent and the red blood cell count to 466 millions. At the end of the three-month period of treatment, the patient's symptoms had disappeared, she had gained weight, in appearance she was lobster-red, her tongue showed a white coat and numerous papillae, and her finger nails were less brittle.

B. CASES WITH AN ASSOCIATED CONDITION

1. Pregnancy—In six cases (2, 5, 10, 13, 14 and 23) there was a history of pregnancy, occurring within six months of the onset of marked symptoms. For some years it has been known that two types of severe anemia (not due to bleeding) may be associated with pregnancy: the "pernicious" type and the "secondary" type.¹⁴ Strauss¹⁵ recently reported three cases of hypochromic or chlorotic anemia of pregnancy, presenting achlorhydria and responding strikingly to large doses of iron. Davies⁸ emphasized the fact that not a few women afflicted with a mild degree of anemia manage quite well until pregnancy supervenes, at which time the anemia and its associated symptoms become prominent. He felt that this was due to a depletion of the mother's iron store, the deficient gastric juice making it difficult of replenishment.

A study of these cases demonstrates that anemia was usually present long before pregnancy had supervened. The same history of pallor of years' duration and former treatment with pills of ferrous carbonate may be obtained as in the completely idiopathic cases. The development of pregnancy appears to act as the extra burden, which, when added to the underlying difficulty in iron absorption, results in anemia.

2. Dysphagia—Patient 3 complained of weakness of several months' standing. For ten years she had been unable to swallow meat because it made her "choke." She was found to have an atrophied tongue, spooned finger nails, dry, gray hair and a moderate degree of hypochromic anemia. Only a trace of free hydrochloric acid was present in the gastric contents. The anemia responded well to meat juices and beef purees, together with small doses of inorganic iron.

The syndrome of dysphagia, weakness and anemia was first described by Paterson¹⁶ and by Kelly¹⁷ but became more widely known after the article of Vinson¹⁸. It is frequently called the Plummer-Vinson syndrome. There is usually a history of long standing dysphagia, manifested as the inability to swallow solid foods, particularly meats, and this is associated with weakness, neurasthenia, dyspnea, anemia and brittle nails.

Suzman¹⁹ has described a series of eight such cases. One of these at postmortem examination disclosed in the tongue, hypopharynx and esophagus a condition of hyperkeratinization of the epithelium with extensive

¹³ This case is fully described in the author's previous publication.⁸

areas of desquamation and, in addition, atrophic degeneration of the underlying muscle tissue. Suzman is of the opinion that the development of the anemia is not attributable to the dysphagia but feels that the underlying cause of all the manifestations of this syndrome is in the nature of a deficiency dependent on a gastric abnormality.

Except for the added feature of dysphagia, there appears to be no difference between the so-called Plummer-Vinson syndrome and the syndrome described in this paper.

3 Gastro-Enterostomy, Gastrectomy—Patients 16 and 25 had marked anemia following operations on the stomach. In both, complete achlorhydria was found. The development of anemia after total gastrectomy is well known. In most cases some degree of anemia develops, which in the great majority is hypochromic rather than hyperchromic (pernicious) in type.²⁰ Recently anemia, together with changes in the tongue and finger nails, has been reported following the operation of gastro-enterostomy, especially when achlorhydria was present (Taylor,²¹ Davies⁸). Morley and Roberts²² feel that the anemia may be associated with the rapid emptying rate of the stomach and with the production of achlorhydria.

4 Myxedema—Two cases, only one of which is included in this report, presented anemia, complete achlorhydria, and myxedema. In one of these patients (patient 22) the anemia did not respond to thyroid extract or to large doses of iron but there was prompt response to a mixture of reduced iron and copper sulphate. Lerman and Means²³ have recently demonstrated that nine of seventeen patients with myxedema showed complete achlorhydria. They point out that there is a direct correlation between the presence of achlorhydria and the degree of anemia. Whether the anemia in the cases of myxedema showing achlorhydria should be classified as "secondary" or grouped with the disease syndrome described in this report is debatable. The decision depends in great part on one's point of view. A study of the anemia per se shows it to be in all respects identical with the syndrome already described. The myxedema may thus be viewed as a contributory cause in the development of the anemia. From the observations of Lerman and Means, it seems probable that, in the presence of a normal gastric juice, anemia is unlikely.

5 Tapeworm—In patient 15, the typical symptoms, signs and anemia were present, together with the history of the passage of tapeworm segments for ten years. Anemia and tapeworm infestation have often been associated. Thus the association of *dibothriocephalus* latus infestation with pernicious anemia has been well known for many years. Although the worm may be the direct etiologic agent, it is possible that it may be only the added stimulus which together with a megaloblastic marrow and a peculiarly defective stomach, brings about the disease known as pernicious anemia.²⁴ In this regard it is well known that, in the great

majority of those harboring the fish tapeworm, anemia does not develop. Castle,²⁵ in his study of the anemias of Puerto Rico, made much the same observations in the anemia of hookworm infestation. He found (1) that while most of the natives harbored hookworms, only a certain percentage had anemia, (2) that riddance of the worms did not significantly alleviate the hypochromic anemia which was frequently associated with achlorhydria, (3) that large doses of inorganic iron resulted in prompt clinical and hematologic improvement even though the worms were not expelled. He feels that the presence of hookworms may be only one of a group of several factors which together result in an iron deficiency and thus in a hypochromic type of anemia. Among these factors he mentions changes in the gastro-intestinal tract, resulting in improper absorption of iron, and perverse or absent appetite resulting in improper dietary. *Taenia saginata* infestation has also been reported as a rare cause not only of pernicious anemia but of a "secondary" anemia as well.²⁶

COMMENT

A Pathogenesis of the Disease—Most authors who have written on this disease are of the opinion that the primary disorder is in the nature of a defective gastro-intestinal tract, usually the stomach, at times the intestine. This defect may lead to insufficient absorption of hemoglobin-containing foods and thus to hypochromic anemia. Experimental support is lent to this view by the work of Mettier and Minot, who found that iron is more potent for blood formation when absorbed from an acid rather than from an alkaline medium within the gastro-intestinal tract. They suggested that the anemia could result from failure over a prolonged period of time in the adjustment of the contents of the upper intestinal tract to a most suitable pH for iron utilization, which could result among other ways from achylia gastrica.

The development of anemia may be intensified or made more rapid by (1) insufficient diet, particularly meat, (2) dysphagia, and (3) such other added factors as pregnancy, myxedema, tapeworm or chronic blood loss. Individuals with achlorhydria appear to possess a defect or vulnerability which in the course of time, especially when these factors are present, may lead to anemia. Several authors have shown that a far greater percentage of individuals with achlorhydria have anemia than those with normal free hydrochloric acid in their gastric contents.²⁷ The abnormality common to all the cases listed is the marked diminution and usually the complete absence of free hydrochloric acid.

Whether the absence of free hydrochloric acid is directly responsible for the development of the anemia, or whether it is merely one among many incidents in a disordered gastro-intestinal tract, cannot be definitely stated at present. That the absence of free acid speaks for a more general disorder of the gastric mucosa is brought out by the careful studies of Davies, who found a markedly diminished content of pepsin, exceedingly low volumes of secretion, and large mucus content. It is, to be sure, possible that a parallel disorder of the intestinal mucosa may be present, resulting in improper absorption of iron. However, the only available evidence of a disordered gastro-intestinal tract

is represented by the changes in the gastric juice. No abnormalities of the stools have been noted except in the occasional patient with diarrhea. The many parallelisms between this disease and pernicious anemia lead one to suspect the absence in primary hypochromic anemia of an unknown factor useful in the digestion of iron-containing foods.

It is possible that the deficiency of iron in the body may result in a lowered function of various body cells and thus in such "trophic" disturbances as atrophied tongue, brittle finger nails, dry hair, and sallow wrinkled skin. In line with these speculations are the fundamental researches of Otto Warburg,²⁸ who has shown that the body cells contain in very minute concentration an iron porphyrin compound. This is highly active and functions as a catalyst, which takes up the oxygen brought to it by the red blood cells and gives it to oxidizable substances within the cell. It is possible that a reduction in the iron content of the body cells may result in their diminution in function, and thus in the "trophic" disturbances previously described (dry, graying hair, atrophic tongue, brittle finger nails).

B. Relation to Pernicious Anemia—In my previous publication, I stressed the close similarity between the syndrome described here and pernicious anemia. In fact, the natural tendency in the past has been to call some of these cases "pernicious anemia" despite their blood picture and despite their lack of response to liver extract. Thus McLester,²⁹ in writing of a group of patients with achlorhydria and anemia, among whom were four with hypochromic anemia, stated (of patient 2) that he was "inclined, in spite of failure to

find typical blood changes, to regard her disease as pernicious anemia." Of the twenty-five cases reported here, six were labeled pernicious anemia or questionable pernicious anemia at the first visit. It is possible that the failure of certain cases of "pernicious anemia" to respond to liver therapy has been due to mistaken diagnosis, primary hypochromic anemia being in reality present. It is easy to see how mistakes may occur, since in both are present a chronic idiopathic anemia

Fig. 3 (case 10)—The tongue about two months after treatment with iron and ammonium citrate was instituted. The appearance is glossy, with absence of papillae and almost complete absence of the normal coat. A small "island" of regenerating papillae is present at the posterior portion of the tongue.

with tendency to spontaneous remissions and relapses, in both there is weakness, sore tongue, gastro-intestinal disturbance, paresthesias. In both there is achlorhydria, in both a hyperplastic marrow, in both there is a leukopenia and a reduction in blood platelets. In pernicious anemia there is defective maturation of

megaloblasts, in primary hypochromic anemia, defective maturation of erythroblasts. The difference in blood picture is probably due to differences in the fundamental pathologic changes of the bone marrow. Since both diseases may be dependent on a defective gastric mucosa, it is theoretically possible that one type may by transition develop into the other. Such was apparently the case in one patient who in February, 1930, had a hypochromic anemia with achlorhydria but who in December, 1930, had a typical hyperchromic anemia responding to liver extract. One other case,

Fig. 4 (case 10)—The tongue about six months after the beginning of treatment. The tongue is now almost normal in appearance, presenting numerous papillae and an abundant coat. The shiny appearance has disappeared except from parts of the edges.

possibly intermediary between primary hypochromic anemia and pernicious anemia, was observed. In this woman, the signs of combined system disease were present. There was achlorhydria and anemia, but the color index was definitely below 1 and the red blood cells showed slight hypochromia. The average red blood cell diameter was 7.4 microns, macrocytes and microcytes both being present. It is possible that some of these cases of hypochromic anemia will ultimately present hyperchromic anemia. The appearance of cases of microcytic and macrocytic anemia in the same family is not rare (Faber and Gram,³⁰ Conner,³¹ Mustelin,³² Patek³³). Faber and Gram³⁰ cite the most remarkable family in this respect. Three generations were studied, anemia and achlorhydria appearing in the first two. One patient passed through the stages of "microcytic" anemia relieved by iron (1919), "latent" pernicious anemia (1928) and full-blown pernicious anemia relieved by liver extract in 1929. Other examples of transition from hypochromic to pernicious anemia are given by Davies³ and by Schaumann and Saltzman.³⁴ It is possible that pernicious anemia and primary hypochromic anemia may be variants of a more general disease characterized by achlorhydria, gastric defect and anemia.

C. Relationship to Chlorosis—Is it possible that the primary anemia described here is chlorosis? Although the latter disease was common in the late decades of the nineteenth century, it is now almost never diagnosed and is universally considered to be defunct. The possible reasons for its disappearance have aroused much unprofitable speculation. Various authors con-

sider that the type of anemia described in this paper is a "present-day" chlorosis (Mills,² Schulten,³ Naegeli⁴) The blood picture in the two conditions is, to be sure, indistinguishable there is in both a marked diminution in hemoglobin as compared with slight or moderate diminution in red blood cells and therefore a low color index, the red blood cells show hypochromia and microcytosis Chlorosis responds quickly to iron medication, as does primary hypochromic anemia Against the concept that one is dealing here with chlorosis are the following features ³⁶ 1 Chlorosis was peculiar to young girls and its existence after the age of 30 was so rare as to be doubted by most authors 2 It was associated with hyperchlorhydria and not achlorhydria 3 It was not associated with a sore or atrophied tongue 4 It was not associated with central nervous symptoms 5 Again, the disease is said to have been ameliorated by pregnancy Despite these features, it cannot be denied that, since both diseases are (a) idiopathic or primary and (b) respond quickly to iron medication, the same pathogenesis may account for the two Bloomfield³⁷ presents several arguments emphasizing "the impossibility of differentiating 'chlorosis' in the nineteenth century sense from the (primary) hypochromic anemia of modern writers" An interesting speculation is that some of the middle-aged women presenting themselves now with hypochromic anemia may have had as girls the other iron deficiency disease—chlorosis It may be helpful to group the three diseases in tabular form (table 4)

TABLE 4—Three Primary Anemias

	Primary Hypochromic Anemia	Pericious Anemia	Chlorosis
Age	Usually in middle aged	Middle to old age	Young girls
Sex	Limited to females	Both sexes	Females
Relapses	Present	Present	Present
Relation of relapse to pregnancy	Frequent	Occasional	No relation
Sore tongue	Frequent	Absent	Absent
Finger nails	Spooned	Normal	?
Hair	Dry often gray	Gray	?
Gastric juice	Achlorhydria	Achlorhydria	Hyperchlorhydria
Color index	Low	High	Low
Red cells	Hypochromia microcytosis	Hypochromia macrocytosis	Hypochromia microcytosis
Active iron	Inorganic iron	Liver extract etc	Inorganic iron

D Is This Secondary Anemia?—The hypochromic blood picture suggests the possibility of secondary anemia As stated in my previous publication, the presence of a low color index and hypochromia does not at once rule out a primary, "idiopathic" or 'essential' anemia (cf chlorosis) nor conversely does the presence of high color index and hyperchromia in an anemic individual rule out the absence of an assignable cause or contributory factor (pregnancy, Dithionitecephalus latus infestation) There can be no doubt about the striking clinical features, when recognized of this syndrome The ordinary case of anemia, secondary to known cause, does not present these features I have recently seen, however, a number of patients who presented such symptoms as glossitis and

spooned finger nails, although their anemia could be definitely assigned to some such cause as carcinoma or chronic loss of blood In these patients, however, complete achlorhydria was found It is therefore possible that primary hypochromic anemia with its various manifestations may represent part of a greater syndrome of iron deficiency ("hypoferrism") and that certain cases of anemia which are definitely secondary may also be included in this syndrome Bloomfield is of the opinion that the cases classed as primary hypochromic anemia and chlorosis constitute a syndrome without fixed characteristics, and conditioned probably by increase in menstrual bleeding

TREATMENT ³⁸

There is no feature of the disease that is quite so striking as the dramatic response to large doses of iron The effect is comparable to that of liver extract in pernicious anemia For the most part, I have used the double salt of iron and ammonium citrate in 25 per cent aqueous solution in doses of from 24 to 30 cc. (6 to 8 Gm) daily Probably because of the ammonium citrate content of the drug, gastro-intestinal disturbances such as nausea, belching and diarrhea are occasionally seen When these occur, reduced iron (FeO) may be used in 1 Gm (15 grain) capsules, from 3 to 6 Gm daily The latter medication is advantageous for several reasons the dosage does not necessitate measurement by the patient, is tasteless and does not cause gastro-intestinal irritation Furthermore, its iron content is manifestly higher as compared with iron and ammonium citrate (reduced iron, 78 per cent iron, iron and ammonium citrate, 17 per cent iron) Smaller doses of reduced iron, probably one-half those of iron and ammonium citrate, may thus be used In about two cases in ten, the precipitate rise in hemoglobin and erythrocytes with iron treatment becomes checked at a level of from 60 to 70 per cent hemoglobin, and there is no further rise even with increase in iron dosage This tendency in the present series of cases was always overcome by the addition of small doses of copper sulphate This drug may be used in solution together with the iron and ammonium citrate or in the capsule with the reduced iron Doses of 0.005 Gm three times a day were ordinarily used Liver extract, gastric extract, and a special "secondary anemia liver fraction"³⁹ were found ineffectual It is my impression that the combinations of liver or gastric extract with iron are no more effective in these cases than is iron alone

The results of treatment with inorganic iron are indeed striking The patient usually experiences on the third or fourth day a marked sense of well being and suddenly acquires a marked appetite, this often becomes ravenous There is almost immediate and rapid gain in weight, in one case (H H) the weight

Fig 5 (case 20) —The tongue during a slight relapse which took place when the patient discontinued iron therapy There is a shiny reddened area at the tip

³⁹ Whipple G H Robscheit Robbins F S and Walden G B Blood Regeneration in Severe Anemia VII A Liver Fraction Potent in Anemia Due to Hemorrhage Am J M Sc 179 628 (May) 1930 The secondary anemia liver fraction was supplied by Eli Lilly & Co

rising from 121 to 162 pounds (55 to 75 Kg) in three months. The sensations of weakness and dyspnea, the soreness of the tongue and the gastro-intestinal disturbances rapidly disappear. Pallor rapidly diminishes so that the change in color of the face and mucous membranes is striking even from week to week. The most remarkable objective changes are those seen in the tongue. Its red, shiny appearance due to absence of papillae gives way in the course of a few months to an appearance that is completely normal. The papillae have regenerated, the shiny red appearance has disappeared, and a normal coat is present (figs 3 and 4). Marked changes in the tongue occur even from week to week. The papillae may at times regenerate in small islands, the entire tongue gradually becoming normal when these islands become confluent. The nails become less brittle, the skin becomes less wrinkled and flabby, and the hair becomes less dry. In one patient with the signs of combined system disease there was slight though definite improvement in the neurologic signs of that disorder.

The blood shows on the third to the fifth day a definite increase in reticulocytes, which reach their peak on the fifth to the seventh day. The blood platelets become markedly increased—in one patient rising from 40,000 to 1,250,000 per cubic millimeter. The white blood cells increase as a result of an augmentation of polymorphonuclears. Most striking, however, is the rise in hemoglobin, which is paralleled by the rise of erythrocyte count. Within two to four months, normal values for hemoglobin and red blood cell counts are reached, and polycythemia may even be produced. There is a tendency to relapse when medication is discontinued, and maintenance doses of about 1 Gm of iron and ammonium citrate or 0.5 Gm of reduced iron daily are required.

SUMMARY

1 The clinical features of twenty-five cases of primary hypochromic anemia were studied.

2 The disease is characterized by the presence in adult women of a chronic idiopathic "secondary" anemia, subject to remissions and relapses.

3 It presents the following clinical features:

Symptoms—Weakness, dyspnea, gastro-intestinal complaints, sore tongue, paresthesias, weight loss.

Signs—Pallor without icterus, wrinkled, atrophied, inelastic skin, glossitis, brittle, often spooned, finger nails, dry, gray hair.

Blood—Anemia of low color index, hypochromia of the red blood cells, small average red blood cell diameter, leukopenia, and reduction in blood platelets.

Gastric Juice—Achlorhydria, usually complete, small volumes, increased mucus.

Response to Medication—Prompt and striking response to large doses of inorganic iron, small doses of copper sulphate of benefit when the anemia becomes "fixed."

4 Certain cases are associated with pregnancy, dysphagia (Plummer-Vinson syndrome), gastrectomy and gastro-enterostomy, myxedema and tapeworm infestation. The common feature is achlorhydria.

5 On the basis of striking response to treatment with inorganic iron there is a possibility that an iron deficiency is present. It is possible that absence of free hydrochloric acid from the gastric juice may result in poor absorption of food iron from the gastro-intestinal tract.

A SUCCESSFUL TREATMENT FOR STRYCHNINE POISONING

REPORT OF ELEVEN CASES

G F KEMPF, M D

J T C McCALLUM, M D

AND

L G ZERFAS, M D

INDIANAPOLIS

The importance of an adequate method for treating strychnine poisoning in man has been stressed editorially in *THE JOURNAL*,¹ and the recent literature reviewed.

Three of the cases in this report were mentioned by Zerfas and McCallum² and are included for a critical analysis of this method of treatment when complicated by the previous use of morphine, apomorphine, ether, or gastric lavage.

A successful treatment for any poisoning must do one of three things: (1) empty the stomach before the poison is absorbed, (2) prevent the absorption of the poison, or (3) counteract the systemic effects of the poison. The stomach pump and various common emetics, including oily substances, have been tried, but the difficulty with this line of treatment, because of the solubility of strychnine, has been that, at the time symptoms are noted, much of the poison has been absorbed and such measures (except possibly the use of apomorphine) either induce convulsions or increase their severity. Lard, oily substances, tannic acid, tannin, potassium permanganate, and dilute iodine have been given with the idea of rendering the strychnine inert or preventing its absorption, but again these are of value only before symptoms are noticed.

Antidotes to counteract the systemic effects of the poison have been given in the attempt to control the convulsions, to eliminate the poison, and to supply oxygen to prevent asphyxia. Death in strychnine poisoning is due either to exhaustion or to asphyxia. Among the antidotes that have been used in an attempt to counteract the systemic effects of this drug are bromides, alcohol, apomorphine, morphine, calabar bean, camphor, nicotine, amyl nitrite, physostigmine, chloral hydrate, paraldehyde, chlorbutanol, chloroform, ordeal nut, atropine, curare, ether and oxygen. Bleeding was once resorted to in an attempt to help eliminate the poison, and, more recently, intravenous saline solution,³ magnesium sulphate, and dextrose have been used with better results on animals. The rhythmic movements of artificial respiration⁴ have been used with good results. In animals, anaphylaxis,⁵ and acidosis⁶ caused by uranium salts, ammonium chloride, and carbon dioxide protect against a lethal dose of strychnine.

From the Lilly Laboratory for Clinical Research, Indianapolis City Hospital and the Department of Medicine, Indiana University School of Medicine.

Drs C B Hathaway, John Emhardt, Jewett Hord, M E Whitlock, H W Goss, D G Bernoske, George Moses, J D Rogers, L W Painter, K C Smithburn, M L Ruth, F F Furstenberg, and E Lamb cooperated in the study of the cases reported.

¹ The Treatment of Strychnine Poisoning editorial, J A M A 98 1992 (June 4) 1932.

⁴ Gies, W J, and Meltzer S J. Artificial Respiration and Strychnine Spasms, *Am J Physiol* 9 1, 1903.

⁵ Arloing F and Langeron L. Action preventive du choc anaphylactique sur l'intoxication expérimentale par la strychnine. *Compt rend Soc de biol* 91 73 (June 20) 1924.

⁶ Wenner W T and Blanchard, E W. The Effect of Acidosis in Strychnine Poisoning, *Am J Physiol* 90 83 88 (Sept) 1929.

Of the antidotes named, ether, chloroform and chloral hydrate are most frequently resorted to today in attempting to control the convulsions. The difficulty with these is that, if the quantity of strychnine absorbed is large, the amount of these drugs required to control the convulsions, once they have started, is apt to be sufficient to depress or stop respiration and thus defeat their purpose. Morphine in sufficient quantity to control the convulsions is likely to prove fatal, and apomorphine,⁷ while useful, may not be adequate.

A drug that can be given intravenously in just a sufficient amount to control the convulsions, which does not in that amount depress the respirations, to which strychnine itself appears to have some powers as an antidote, and which does not markedly depress the circulation, would seem to meet the requirements of an ideal antidote for strychnine. With such an antidote, the questions of exhaustion and asphyxia take care of themselves, and elimination, which usually continues by way of the kidneys for about three days,⁸ may be disregarded.

REPORT OF CASES

Ten cases in which sodium isoamylethylbarbiturate (sodium amytal) and one in which sodium pentobarbital was used are presented.

CASE 1—V H, a white woman, aged 19, well developed and well nourished, was brought into the Indianapolis City Hospital at 5 15 p m, Oct. 26, 1928. She had taken 100 one-thirtieth grain (0.002 Gm) strychnine sulphate tablets at 1 p m after a heavy meal. She had been given morphine one-half grain (0.03 Gm), hypodermically, about fifteen minutes before admission. She was having mild convulsive twitchings at this time and an attempt at gastric lavage was made. She immediately had a severe generalized convulsion with opisthotonos, trismus, risus sardonicus, complete extension of the extremities, and cyanosis. Attempts to induce ether anesthesia increased the convulsions. She had five such convulsions in fifteen minutes, and, during the fifth, she was given 8½ grains (0.55 Gm) of sodium amytal intravenously. The convulsion stopped and the patient relaxed completely and went to sleep. At 7 30 the patient aroused, drank a glass of water, and dropped back to sleep. She roused slightly at 10 o'clock and, at this time, appeared to be slightly hypersensitive, but she soon fell asleep again and had no further convulsions. She was transferred to the ward where for two days she suffered from a rather severe gastritis, which caused her to vomit frequently. On the third day she was normal and was released from the hospital. This is the first case of strychnine poisoning treated with sodium amytal.

CASE 2—J B, a white man, aged 20, a soldier, took 200 one-thirtieth grain (0.002 Gm) chocolate coated strychnine sulphate tablets at about 4 15 p m, Feb. 10, 1929. He was said to have had one convulsion from which he became cyanotic before the physician arrived at 4 45, at which time he was given one-fourth grain (0.016 Gm) of morphine hypodermically. At 4 50 he was given a gastric lavage at the Indianapolis City Hospital, and, between 5 05 and 5 25, he had mild muscular twitchings which gradually increased. Before they became complete, however, he was given 12 grains (0.78 Gm) of sodium amytal intravenously. This was sufficient to relax him completely and put him to sleep. He awakened at 8 o'clock and complained of being hot but he dropped back to sleep. He aroused several times, and at 10 o'clock he vomited after drinking a glass of water. He showed no signs of irritability from strychnine after the administration of sodium amytal and the following morning awakened feeling very thirsty and slightly weak. At 11 a m he was able to walk unassisted to the military ambulance.

CASE 3—B O, a white woman, aged 24, well developed and well nourished, was admitted to the Indianapolis City Hospital, June 24, 1929, within an hour after taking ten strychnine tablet triturates, which were of not less than one-half grain (0.03 Gm) each. Apomorphine, one-sixth grain (0.01 Gm), was administered by a physician about half an hour after she took the strychnine. Morphine, one-fourth grain, was given in the home by the ambulance physician, and, during the trip to the hospital, she had three convulsions, during which she completely emptied her stomach and during which she became cyanotic. At the hospital she was given another one-fourth grain of morphine, which did not control her convulsions. Some twenty minutes later she was given 10 grains (0.65 Gm) of sodium amytal intravenously. She immediately relaxed and fell asleep. The patient slept all night and most of the next day, on the evening of which she signed her own release and went home.

CASE 4—R M, a white man, aged 56, well developed and fairly well preserved, was admitted to the Indianapolis City Hospital, Feb. 19, 1930, at 8 30 a m, after having taken 2 grains (0.13 Gm) of strychnine at 7 30 a m. On admission the temperature was 101 F, the pulse 140 and rate of respiration 32, he was having muscular twitchings and mild convulsions. At 8 45 he was given 7½ grains (0.5 Gm) of sodium amytal intravenously. He relaxed and slept until 10 o'clock, when he awakened and had three mild convulsions in about thirty minutes. The patient's stomach had not been pumped and it was not washed later, so the 2 grains of strychnine that he had taken was absorbed. The convulsions were increasing in severity, so, at 10 40, another 7½ grains of sodium amytal was given intravenously, after which he relaxed and went to sleep. At 11 30 he could be partly aroused, but he did not show signs of strychnine irritation. He slept until about 5 p m, when he awakened sufficiently to take small amounts of fluids. The temperature, pulse and respiration rate were 100, 120, 28, respectively. After this, he slept most of the night. The next morning he complained of some stiffness of the muscles, which apparently was due to the severe contractions during the convulsions of the previous day. He was able to sit up and was sent home, apparently in good condition, that afternoon.

CASE 5—L R, a white man, aged 19, well developed and well nourished, with a palpable thyroid, took 3 grains (0.2 Gm) of powdered strychnine sulphate in a gelatin capsule at 11 p m, April 15, 1930, and had a convulsion at 11 30. This convulsion was controlled with ether, and the patient was transferred to the hospital under anesthesia. At 11 45 he was markedly hypersensitive, mentally very alert, and apprehensive. At this time he was given intravenously 15 grains (1 Gm) of sodium amytal, which was sufficient to produce sound sleep. At 3 30 a m, April 16, the patient was completely awake, described to the nurse his convulsion, and complained of extreme thirst. Ten minutes later he began twitching at intervals, and twenty minutes later he had a severe convulsion, lasting three minutes, after which he fell asleep. At 5 o'clock he was hypersensitive and was given 7½ grains of sodium amytal intravenously, from which he awakened fully at 10 30. Although the patient did not have a gastric lavage, he complained of nausea and gastric distress, and at 5 p m he vomited. At this time he also complained of feeling very tired and of cramps in his muscles. April 17, at 9 30 a m he again vomited, but he was able to eat at noon and did not show further evidence of gastritis. His condition was apparently good, April 18 and on April 19 he was released. Urine specimens for three days contained strychnine.

CASE 6—M D, a white woman, aged 30, well developed and well nourished, apparently in good physical condition, took a quantity known to be more than 8 and less than 12 grains of powdered strychnine sulphate at about 2 30 a m, May 27, 1930. About 2 45 she began to have twitchings and mild convulsions, and she was brought into the hospital at 3 20 in complete convulsions with opisthotonos and cyanosis. Seven and one-half grains of sodium amytal given intravenously at 3 30 was sufficient to quiet her, but not enough to allow a gastric lavage. At 3 40, after another 7½ grains of sodium amytal had been given intravenously, a gastric lavage was done and the stomach found empty. The patient was partly awake and attempted to vomit after the lavage. She remained quiet

until about 4 15, when she began groaning and having muscular twitchings Six grains (0.4 Gm) of sodium amytal intravenously at 4 20 was sufficient to keep her asleep until we attempted to give her an intravenous injection of physiologic solution of sodium chloride at 5 30 She was given 7½ grains of sodium amytal followed by 750 cc of physiologic solution of sodium chloride intravenously with the idea of increasing diuresis In spite of the fact that she had had 28½ grains (1.8 Gm) of sodium amytal intravenously between 3 30 and 5 30, she was awake at 7 30 She was very groggy from the sodium amytal but did not show hypersensitivity from strychnine At 9 o'clock she was given a high colonic flushing with a gallon of tap water and did not show any signs of strychnine poisoning during the process During the morning she was awake and restless but slept at intervals, and during the afternoon and that night she slept very well The next day she was awake and rational but complained of some gastric pain and of sore muscles, which disappeared during the day She was released the following day, May 29, in good condition and apparently fully recovered

CASE 7—E W, a white woman, aged 20, apparently normal, was admitted, Aug 27, 1930, to the Indianapolis City Hospital approximately half an hour after taking two one-fourth grain tablet triturates of strychnine sulphate on an empty stomach While in the ambulance she became markedly hypersensitive and began having muscular twitchings, for this reason she was

in convulsions and showed only hypersensitivity She was given 6 grains (0.4 Gm) of sodium amytal by mouth at 1 35 p m, and at 3 o'clock one-fourth grain of morphine Because of mild convulsions, at 3, 5 10 and 6 30, she was given 9 grains (0.6 Gm) of sodium amytal by mouth At 6 50 she was again in convulsions and at this time was given 6 grains of sodium amytal intravenously At 8 o'clock she required another 7½ grains intravenously The patient slept until 3 p m the following day She was apparently well at the end of the third day and was dismissed from the hospital on the sixth day

Case 9 is interesting, as 33 grains (2.1 Gm) of sodium amytal had to be given by mouth, because a sterile ampule was not available, and in that 13½ grains (0.87 Gm) had to be administered intravenously later This patient might have been spared the large dose of 46½ grains (3 Gm) of sodium amytal had it been used intravenously in the first place However, she probably had ingested much more than 8 grains of strychnine

CASE 10—L S, a white man, aged 33, took 8 grains of powdered strychnine at about 7 a m, April 4, 1932 He was brought to the Indianapolis City Hospital immediately and his convulsions were controlled with ether He was allowed

Analysis of Eleven Cases of Strychnine Poisoning with Recovery

Case	Date	Age	Weight		Strychnine, Amount Ingested				Sodium Amytal, Amount Required				Other Treatment				Gastric Lavage

8 V H	11/22/30	4	40	18.2	?	?	?	?	15	972	53.4	?					
										Pentobarbital	-						
11 W T	11/24/30	48	100	72.7	1¼	51	1.11	1.58	7.5	486	6.65	4.22					

Case 9, 33 of 46.5 grains of sodium amytal were given orally case 10, 6 of 21 grains of sodium amytal were given orally Calculations were based on 0.7 mg of strychnine sulphate per kilogram as the minimal lethal dose 2.2 pounds = 1 Kg, 1 grain = 64.8 mg

given two one-fourth grains of morphine sulphate when she reached the hospital About five minutes after this she was given 7½ grains of sodium amytal intravenously, which was sufficient to put her soundly to sleep She awakened at about 8 p m and was given water and 4½ grains (0.3 Gm) of amytal by mouth The patient's stomach was not washed She awakened in the morning and expressed the desire to go home She was released in apparently good condition

CASE 8—V H, a white boy, aged 4 years, while at play, Nov 21, 1930, took an unknown number of "red tablets" About 11 a m he began having convulsions and was brought into the hospital The ambulance physician immediately gave the child 15 grains of sodium amytal intravenously and he slept until 6 30 a m, November 22 Gastric lavage was not done The temperature and pulse were elevated on the day of admission, but abnormalities were not noted the following five days, during which the child was kept for observation The parents described the convulsions as a complete stiffening out, which came on at intervals and continued with increasing frequency

Case 8 is described because it was an accidental one in which there was uncertainty about the dosage, and the amount of sodium amytal was governed entirely by that required to induce complete sleep

CASE 9—M S, a white woman, aged 28, was admitted to the Indianapolis City Hospital, Jan 16, 1932 after having taken more than 8 grains (0.5 Gm) of strychnine She was not

to awaken and was given intravenously 7½ grains of sodium amytal He did not go to sleep and was given 750 cc of physiologic solution of sodium chloride At noon he became markedly hypersensitive and had a slight convulsion Seven and one-half grains of sodium amytal administered intravenously was sufficient to quiet him but did not put him to sleep At 4 45 p m and again at 8 o'clock he was given 3 grains (0.2 Gm) by mouth because of slight hypersensitivity The patient rested well during the night and was released on the third day without further symptoms

CASE 11—W T, a white man, aged 48, took 1¼ grains (0.08 Gm) of strychnine in the form of one-fourth grain tablet triturates at 2 00 a m, Nov 24, 1930 He was hyperexcitable but did not have a complete convulsion He was given 7½ grains of pentobarbital sodium intravenously and slept until 5 30 There were no further symptoms and the patient was released after twenty-four hours This is the first case of strychnine poisoning to be treated with pentobarbital sodium

COMMENT

An analysis of the cases does not indicate that morphine had any appreciable influence on the action of the poison The patients who received morphine, and particularly the one who also received apomorphine, were more depressed Apomorphine did not minimize the patient's convulsions Ether is useful, but a review of previous cases in this hospital shows that, in one

patient, pneumonia (following aspiration of material from the stomach) caused death five days after ingestion of strychnine. Gastric lavage or the use of emetics is unnecessary.

When the data in human cases are compared with the data on animals⁹ the important point that human beings per pound or per kilogram are much more sensitive to the barbiturates is illustrated. From 5 to 10 mg per kilogram will not induce sleep in a rabbit and will not protect it from a single lethal dose of strychnine, while in human beings that amount is sufficient. This corresponds to the experience with barbiturates when used as an anesthetic on man and on animals. That the greater doses of strychnine require proportionately smaller amounts of barbiturate is clearly illustrated in the analyses of the cases treated with sodium amytal. Animal experiments indicate that sodium barbital acts too slowly to be effective when given after the onset of convulsions due to large doses of strychnine.

The comparative results on patients also illustrate the variation in susceptibility to the action of sodium amytal or to strychnine and the importance of giving intravenously a quantity just sufficient to stop the convulsions. The feasibility of having the antidote ready and awaiting symptoms becomes important when doubt exists as to whether strychnine has actually been ingested and when one is afraid of masking the action of another poison.

In only three of the cases were we able to ascertain the amount of strychnine ingested before it was necessary to administer the antidote. In most cases of accidental poisoning, particularly in children, the amount of strychnine taken is not known, and those taking it with suicidal intent frequently will not or cannot give this information.

A drug that can be given in quantity just sufficient to stop convulsions and in such a manner that a definite result may be obtained at once is almost necessary to save life. A soluble barbiturate, such as sodium amytal, sodium pentobarbital or phenobarbital sodium, is the only available drug that can, on present evidence, be safely used in this manner on human beings.

The following directions for the use of sodium amytal, sodium pentobarbital or phenobarbital sodium, based on eleven cases, and the results of animal experiments are given:

1 When sodium amytal or sodium pentobarbital is used, just enough of the intravenous preparation is given to put the patient to sleep or, if in convulsions, to stop them. (The patient will usually go to sleep).

2 When phenobarbital sodium is used, a quantity just sufficient to stop convulsions should be given, even though sleep is not induced.

3 When the patient shows further symptoms of strychnine poisoning, as indicated by heightened reflexes, complaints about noises, marked response to slight stimuli, or convulsions, the antidote should be repeated.

4 Gastric lavage is unnecessary and not advisable but may be done after the patient is asleep if adequate help is available to prevent injury or aspiration of material from the stomach.

⁹ Based on experimental work on rabbits in the Lilly Laboratory for Clinical Research, Indianapolis City Hospital and on work reported by Dawson W. T. and Taft C. H. Jr. *Suppression of Strychnine Convulsions by Barbiturates* Proc. Soc. Exper. Biol. & Med. 28: 91 (June) 1931.

Bailey O. W. *The Effectiveness of Pentobarbital in Antidoting Strychnine Poisoning in the Rabbit* J. A. M. A. 98: 1923 (June 7) 1932.

5 Physiologic solution of sodium chloride may be given intravenously, but this is not necessary.

6 Quiet, dark surroundings are recommended.

7 One should distinguish between the effects of the barbiturate and the action of strychnine when repeating the injection. This may occasionally present a real difficulty, and, when doubt exists, it is wise to await a mild convulsion before giving the second or third dose of barbiturate.

8 The dose to be given cannot be calculated unless one is definitely certain of the amount of strychnine ingested, the amount of strychnine absorbed, and the weight of the patient. Idiosyncrasy to either the poison or the antidote may then change it.

9 Morphine is not indicated and apomorphine may prove dangerous in that aspiration of material from the stomach may occur.

10 Ether may well be used to control convulsions until a soluble barbiturate can be given.

11 Should an intravenous preparation not be available and the patient not be in convulsions, amytal, phenobarbital, pentobarbital, or other barbiturates may be given by mouth, the amount not to exceed the equivalent of 15 grains of sodium amytal for an adult. The intravenous preparation can then be given later, if necessary.

CONCLUSIONS

1 Eleven cases of strychnine poisoning were treated successfully.

2 Sodium amytal and sodium pentobarbital given intravenously are definite life saving measures in strychnine poisoning in man.

Indianapolis City Hospital

NONOBSTRUCTIVE EMPHYSEMA

W. B. KOUNTZ, M.D.

AND

H. L. ALEXANDER, M.D.

ST. LOUIS

It has been generally believed that the underlying lesion of emphysema is primarily in the lungs. Freund's¹ contention that the disease is not essentially a pulmonary disorder but is produced by ossification of the costal cartilages and ankylosis of the costovertebral junctions has been much discussed but has received little support from more recent anatomic investigations. Two clinical types of emphysema have long been recognized. One is associated with bronchial obstruction, the other, the nonobstructive type, which has received relatively little attention, has been called "senile" or "arteriosclerotic" emphysema and has been attributed to degenerative changes in the pulmonary tissue. This investigation is concerned with the second type of the disease.

EXPERIMENTAL

At the outset the respiratory function of patients with nonobstructive or senile emphysema was compared with that of normal controls and with that of patients with bronchial obstruction.

In nonobstructive emphysema, it was noted that abdominal breathing was far more prominent than in the obstructive variety. This clinical impression was confirmed by fluoroscopic observations of the chest. The diaphragmatic excursion was greatly increased when compared to that of obstructive emphysema (fig 1). Particularly was this true when the compari-

¹ Freund W. A. *Verhandl. d. phys. med. Gesellsch.* 9: 223 1859.

son was made during periods of bronchial obstruction. Moreover, in nonobstructive emphysema the diaphragmatic movements were found to be greater than those of normal individuals. The maximum excursion observed was 16 cm. In patients with pronounced

Fig 1—An orthodiagram of maximum respiration in a case of non obstructive emphysema. The diaphragmatic activity is not impaired.

Fig 2—An orthodiagram of maximum respiration in a case of asthma with emphysema. There is marked reduction in diaphragmatic activity as compared to figure 1. These two patients were of the same general body type.

obstructive emphysema the diaphragmatic activity was diminished at times to 1 cm during deep inspiration (fig 2). Occasionally, in such cases, paradoxical movements of the diaphragm were observed.

The activity of the abdominal muscles compared to that of the chest muscles could be graphically recorded. The method consisted in placing rubber tubes of sturdy wall construction around the chest at the level of the junction of the fourth rib with the sternum, and around the abdomen 6 cm below the xiphoid cartilage. Closed circuits were made by joining the ends of the tubes. They were connected to rubber tambours, whose movements were recorded on a kymograph, and the apparatus

Fig 3—Patient with typical nonobstructive emphysema (due to disease of the thoracic spine).

was standardized so that there was a constant ratio between the force exerted on the tubes and the excursion on the drum. Simultaneous records were taken of abdominal and chest movements. The patients inhaled through a spirometer, and a measured amount of air was taken into the lungs. Quiet, moderate and deep respirations were recorded.

Tracings of obstructive emphysema showed a definite preponderance of activity of the chest wall compared to that of the abdomen. Even with attempted deep inspiration, there was little abdominal excursion. Conversely, the tracings of patients with nonobstructive emphysema demonstrated increased excursion of the abdominal muscles in contrast to diminished chest movement. Englehart,² in a study of respiratory motions, has obtained similar records in senile emphysema. When the tracings of both types of emphysema were compared to those obtained from the normal individual, it was found that in nonobstructive emphysema the abdominal activity was greatly increased, whereas in the obstructive type the thoracic excursion was greater than in the normal. As is well known, the movement of the chest compared to that of the abdomen varies in normal individuals, but the ratio is roughly one to one.

Further functional studies on each type of emphysema were compared. These included observations of the vital capacity, the oxygen and carbon dioxide con-

Fig 4—A, outline of roentgenogram (lateral view) of thoracic spine in nonobstructive emphysema, showing the straight poker appearance. B, outline of a similar roentgenogram in a patient with obstructive emphysema. The continuous curve of the thoracic spine may be noted.

tent of the arterial blood, the venous and arterial blood pressures, and response to increased carbon dioxide in the inspired air as shown in the tables.

The vital capacity is reduced in both types of advanced emphysema. It is, however, relatively more reduced in the obstructive than in the senile form. In the cases recorded in the tables, the percentage of normal in obstructive emphysema averages 55, while in the nonobstructive type it is 85. The arterial blood pressure is usually low in obstructive emphysema but is apt to be elevated in the senile type, which usually occurs in older people, and an associated arteriosclerosis is common. The venous pressures were found to be increased in obstructive emphysema but normal in the nonobstructive form. In obstructive emphysema the oxygen content of the arterial blood is low, even with the patient at rest, while the carbon dioxide content may be increased. In contrast to this, the oxygen saturation of the arterial blood was recorded always as normal in senile emphysema, and likewise the carbon dioxide concentration was found to be well within normal limits.

The tolerance for increased carbon dioxide in the inspired air in patients with each type of emphysema was studied. Scott³ has shown that individuals with obstructive emphysema can tolerate a considerable increase in carbon dioxide without great discomfort. It

one constant lesion is straightness and stiffness of the thoracic spine. This is particularly true in the early stages of the disease. Although this deformity is not always obvious on an inspection of the patient, it may be readily observed on lateral views of roentgenograms of the chest (fig 4) and at autopsy. In contrast to this straightening, the roentgenograms of the spine of obstructive emphysema show a continuous curve.

TABLE 2—Obstructive Emphysema

10	2,790	72.0	130/85	13.5	10.0	90.0

* Based on Dreyer's tables.

The mechanism by which the spine assumes a more vertical position, and the influence of this deformity on the thoracic cage, was studied both clinically and pathologically. It was found that as the thoracic spine straightens the vertebral bodies separate. As the ribs are attached posteriorly to the vertebral bodies, straightening of the dorsal spine causes a separation of the ribs and a barrel shaped chest is thus produced. It is possible to demonstrate the effect of a straight thoracic

Fig 5—Chest of a normal cadaver from which all muscle has been removed. The position of the sternum is particularly noteworthy. Its upper edge stands at 15 1/4 inches on the scale.

was found that patients with nonobstructive emphysema could not stand this increase. Their response to carbon dioxide was normal, or sometimes less than normal.

From these studies, it is apparent that nonobstructive emphysema leads to very little impairment in respiratory

Based on Dreyer's tables.

function, which throws much doubt on the supposition that the condition is primarily a disease of the lung. Some other explanation for the barrel chest and the hyperresonant percussion note in nonobstructive emphysema therefore was sought. It was soon noted that

Fig 6—The same model as in figure 5. The thoracic spine has been straightened. The upper edge of the sternum has been raised to 17 inches. At the same time the depth of the chest from the spine to the sternum has been increased 3 cm.

spine on the size of the chest cavity by removing all the muscles from the spine and thoracic cage of a normal cadaver and setting the base of the spine and pelvic bones in plaster of paris. When the spine is straightened so that the thoracic curve is lost, the sternum

elevates and the horizontal thoracic diameters increase (figs 5 and 6)

The spine and bony framework of the thorax of individuals who had nonobstructive emphysema were examined post mortem. Particular inquiry was made to determine whether the costal cartilages were prematurely ossified, and also to see whether there was

Fig 7—Cross section of disks from a case of nonobstructive emphysema. The vertical diameter of the disks measured more than twice normal.

fixation of the costovertebral joints. Ossification of the costal cartilages occurred in 70 per cent of cases of advanced nonobstructive emphysema but was no more frequent than in individuals of the same age group who did not have emphysema. Ankylosis of the costovertebral joints occurred in 20 per cent of our cases. If the view advanced by Freund were correct, one would expect to find ossified costal cartilages in all cases of emphysema of the nonobstructive type.

The most constant lesion found was disease of the intervertebral disks. This was manifested as a generalized degeneration, with swelling a marked feature. The earliest change observed was swelling in the region of the nucleus, which spread outward over the annulus lamellosus. This early process could be seen in some of the disks of a given case, while in others the degeneration was more advanced and the entire disk substance swollen. On gross inspection of a disk cut across, large fissures appeared between lumps of degen-

Fig 8—Sections of intervertebral disks. A, cartilage taken from a case of nonobstructive emphysema, showing (1) loss of cellular outline, (2) cavities within the substance of the cartilage, B, normal cartilage.

erated tissue. There was usually a ring of fairly healthy annular tissue left around the edge. This corresponded to the epithelial ring.

Under the microscope, the degenerative process in the cartilage was readily seen. Large fissures were present and also areas of structureless tissue that took an acid stain.

In some disks the process had advanced to the extent that the disk became functionless and completely separated from the bone. The cut surface then showed the

cartilaginous plate of the vertebral body covered with large areas of degenerated disk remnants. The layers of the annular lamella were so involved at times that the still healthy fibers were torn away from the bone at points of degeneration. Calcium deposits were occasionally observed in the degenerated disks, and these could be recognized in roentgenograms. Hemorrhage into the disks with pigmentation occurred occasionally. Eventually, the fibers and disk substance are found to undergo complete dissolution. In writing on diseases of the intervertebral disks, Beadle⁴ and Schmorl⁵ have described these lesions in great detail.

As the degenerative disease of the disk progresses, the vertebral bodies become more and more invaded by the process and finally thin out. This lesion may reach the stage at which the spine can no longer support its burden, and collapse at some point then occurs. This is found in patients in whom the degenerative process is far advanced. The upper thoracic region is most commonly affected.

When the spine collapses, kyphosis results, and the marked hump in these advanced cases of senile emphysema is a familiar clinical picture. When this occurs, the upper spine sinks away from the upper end of the sternum, which is held forward by the clavicles. The anteroposterior diameter of the chest is thus increased, and at the same time the vertical measurement of the spine is shortened. In individuals who present a kyphosis of this type, a history of loss of height may be obtained. To compensate for the shortening of the thoracic spine, the ribs flare outward and accentuate the barrel chest already present (fig 10).

Fig 9—Section of the thoracic spine, showing the anatomic lesions of nonobstructive emphysema in the advanced stage. Note the angulation between the fourth and fifth dorsal vertebrae due to erosion of the vertebral bodies by the diseased disk.

COMMENT

Other investigators have likewise attributed the mechanism of the production of nonobstructive emphysema to abnormalities of the thoracic cage. Hofbauer⁶ suggested that emphysema with a fixed chest is due to overaction of the inspiratory muscles over those of expiration. The chest thereby gradually distends and mobilizes. We find no experimental or definite clinical evidence to support his theory.

Creyx⁷ believed he could demonstrate degenerative changes in the intercostal muscles when measured by response to electrical stimuli. He assumed that this permitted an abnormal position of the thoracic cage, which assumed the inspiratory position. We repeated Creyx's experiments, and although there is some evidence to suggest a weakness of the muscles of

respiration, we believe with Clement⁸ that such muscle degeneration is a result of bony deformity and is a secondary phenomenon rather than a primary disease of the muscle.

Freund's¹ contention that emphysema is due to ossification of the costal cartilages and to fixation of the costovertebral bodies could not be substantiated. A high incidence of the supposed etiologic factor would be expected, whereas it is discernible in but 70 per cent. Moreover, as was pointed out by von Salis,⁹ it is necessary, in order to mobilize the thorax by rib fixation, that the costovertebral joints likewise be ankylosed. This lesion occurred in but 20 per cent of our series. We therefore infer that these factors do not play an important rôle in the etiology of emphysema.

From the evidence here presented, we believe that in nonobstructive emphysema the lungs shift their posi-

SUMMARY

1 Two types of emphysema are recognized, the obstructive and the senile, or nonobstructive. Obstructive emphysema is characterized by large lungs and by impairment of respiratory function. An associated history of bronchial obstruction is usual. In nonobstructive emphysema there is very little, if any, increase in size of the lung, and but little loss of respiratory function.

2 Nonobstructive emphysema is not primarily a pulmonary disease but merely a change in the position of the lungs secondary to an increase in the size of the thoracic cage. In the advanced cases, alveolar distention with loss of elasticity occurs.

3 The thoracic deformity is due to a straightening of the dorsal spine with kyphosis in the later stages.

4 The underlying lesion is a degenerative process in the intervertebral disks.

THOMSEN'S DISEASE (MYOTONIA CONGENITA)

REPORT OF CASE AND REVIEW OF
AMERICAN LITERATURE

SMITH ELY JELLIFFE, M.D.

NEW YORK

AND

LLOYD ZIEGLER, M.D.

ALBANY, N. Y.

Fig. 10—The same model as figures 5 and 6 with the thoracic spine in an upright position. A portion of the fourth dorsal vertebra has been removed. Pressure is being directed downward and forward. The sternum is raised to above 17 1/4 inches on the scale. The depth of the chest at the same time has been increased 8 cm.

tion as the thoracic cage enlarges. The lateral diameters increase and the vertical diameters become shortened. This is reflected by an elevation of the domes of the diaphragm. If any actual lung distention occurs before the thoracic deformity becomes pronounced, it is not comparable to true emphysema for there is little loss of respiratory function, and when the chest is opened the lungs promptly collapse. In the advanced stages, especially with kyphosis, there is little question that the lungs are distended and even may be so stretched that alveolar rupture occurs and the elastic recoil is impaired. The process by which this lesion is produced is very different, however, from that of obstructive emphysema, which is primarily a pulmonary disorder.

Although the participation of senile degenerative changes in the lung may play some part in the production of nonobstructive emphysema, this is probably a secondary one.

About ten years ago (1922) one of us (S. E. J.) became acquainted through business channels with N. B., who lived several hours out of New York and who came under observation more as a friend than as a patient. Later, through the cooperation of Dr. Ziegler, an opportunity was afforded for a more detailed examination, and this preliminary report is offered, chiefly because of the comparative rarity of reports in American literature on this strange and intriguing malady.

It may be of some interest, noted by Pelz in his description of the atypical forms of Thomsen's disorder, that Erb, who has given the syndrome its most complete description, has written that one is weary with the monotony of the observations in this interesting malady.

In spite of this, and with no specific intention of hoping to add much to the subject, the present contribution is offered with the following thoughts: 1 In looking over various observations we were struck with a family resemblance in a photograph published by Wertheim Salomonson in 1897 of an "Adriaan de B.", and since the initials "de B." also occur in the name of the ascendants of our patient (de Boer) some contact may be established with the Dutch ancestral tree if it should be that the Wertheim Salomonson (Stumpff) case could be connected and the family tree found to be the same. 2 A brief resume may be offered of all the cases reported by American observers. 3 A still further wish on our part is that ultimately a contribution may be made in the psychologic field, which up to the present time has been definitely unexplored. This last consideration brings before the mental eye a not unrelated notion presented by the original describer himself, for it will be recalled that Thomsen was inclined to

⁸ Clement, Keert. *Presse med.* 36: 1647 (Dec. 26) 1925.
⁹ Von Salis, quoted by Clement.

emphasize what in his day might be called psychic factors, as may be seen in his final choice of a description, influenced, it may be, by Bartels (cited by Nissen) "Tonische Krämpfe in willkürlich beweglichen Muskeln in folge von erbter psychischen Disposition" (tonic spasms in voluntary muscles resulting from congenital psychic predisposition)

With reference to this threefold purpose it may be reported that inquiries are in progress to attempt to trace the Holland forebears. Secondly, this paper fulfils the object set forth, namely, the reporting of the American cases. As to the further investigation of possible psychogenic factors, this will be left to a later communication.

REVIEW OF AMERICAN LITERATURE

Some of the more general historical features have been covered up to 1887 in the paper by Jacoby,¹ and a fuller exposition is not necessary at this time. It has been thought of interest to discuss briefly the cases appearing in the American literature.

Engel² is frequently accredited with having offered the first report of a case in American literature. Jacoby has shown, however, that this is a doubtful case, as the disorder first appeared suddenly when the patient was 17 years of age, following an electric shock, and involved the lower extremities only and in a manner different from the true Thomsen type. Moreover, there was no hereditary history. This case may be rejected unless one includes it with certain cases of myotonia acquisita (Talma), examples of which Jacoby himself reported sixteen years later. In 1884, Workman gave a translation of some recent works and said he had seen a case. He reviewed Longuet's work and abstracted other historical studies.

The early reported case of McLane Hamilton³ also presented question marks and, according to Jacoby, Hamilton himself grouped his case with paralysis agitans rather than with myotonia congenita.

Jacoby's first case (1886) is classic and his description and discussion admirable, save that he could not ascertain any hereditary involvement, but he did include a most thorough report of a bit of excised quadriceps femoris muscle, Willy Meyer showing the classic changes described by Erb and others. Jacoby's description of the myotonic reaction is most thorough, and his remarks on the probable presence of embryonic sarcoblasts is of considerable interest in view of later theoretical considerations and also in regard to Erb's discussion along related lines. He writes (p. 151)

In Thomsen's disease, the motor nerves and motor endplates do not show any deviations from the normal. The nerve-impulse, therefore, is transmitted into the muscle-fiber in the same manner as in the normal condition.

The result of this reception of impulse will be a contraction which, especially after a certain rest, will be a hypercontraction, or rather tetanus. This tetanus leads to an agglomeration of a certain number of sarcois elements, with a break in the continuity of the contracted clusters, as can be plainly seen under the microscope. In consequence of this tetanus, the nerve-influence is inhibited for so long as the tetanus lasts. After the lapse of a few seconds, the tetanic contraction will subside, the continuity between the hitherto separated groups of sarcois elements will become reestablished, and the propagation of nerve-influence again rendered possible. If now, in the light

of our microscopical revelations and in consideration of the above theory, we reconsider the objective symptoms found in Thomsen's disease, we are able to understand the production of a great many of them. That the muscle becomes tetanic under the influence of the will has been explained, that mechanical and electrical stimuli applied to the muscles themselves produce a prolonged contraction is also understood, but how it is that stimuli applied to the nerve do not have the same action as those applied to the muscle is not so clear. This much is certain that the cause for this variation must be sought in some change in the nerves themselves, and not in the muscles, probably a change in their molecular arrangement, for microscopically the nerve terminations appear normal, and it is after all possible that later observations may discover changes either in the peripheral or central nervous system, which will take this peculiar affection out of the domain of primary muscular disorders to which it now appears to belong.

Dana's⁴ case, reported a year later (1887), seems atypical.

In 1886, W. A. Hammond⁵ reported the case of D. Leiden. The patient, a man, aged 28, had a brother who was similarly involved. There were no personal histories.

Moyer's⁶ case, reported in 1890, is also an atypical one. W. H., a man, aged 25, first seen in 1884, had no familial history and first noted typical intention holding at the age of 23. On first arising in the morning he did not suffer, but as the day progressed the myotonic state developed.

Hughes,⁷ in the same year, reported what seems also an atypical case. J. H. M., a man, aged 23, first noted his difficulty at the age of 20. He noted that when he attempted to put his pipe in his mouth his arms and hands would not go up. Spasms occurred in his legs which could be walked off. No hereditary aspects were mentioned. Shaw and Fleming⁸ reported the same case in much the same manner as Hughes.

Smith,⁹ in 1894, gave a clinical lecture on a patient with a disorder of the spinal cord, showing also some myotonic reactions. These developed after a fall, when he was at least 67 years of age, which caused complete paraplegia. Since this he had had cramplike myotonic reactions on initiating movements of the legs. It was not a case of Thomsen's disease.

Haynes,¹⁰ in 1897, presented a man, aged 28, who at the age of 7 first noted difficulties in speech and on protrusion of his tongue, later, following alcoholic excesses and an attack of typhoid, he became nervous and had choking spells when swallowing. This was not a case of myotonia congenita.

Preston,¹¹ in 1898, reported the case of H., a man, aged 21, whose mother had had cramps. As far back as the patient could remember he had the peculiar myotonic stiffness on initiating any movement. He had never been able to join in play. He would start to run and fall, the hand grasp would not open, the eyes would be "set," and the abdominal muscles were also involved.

It became worse in wet weather. There was well developed musculature. Electrical reactions were not absolutely typical.

Mills,¹² writing in 1891 on myotonia and inertia of voluntary effort, reported the case of a man, aged 40, who as a boy of 10 recalled that he had had the typical myotonic condition in his hands, feet, jaw and elsewhere. There were muscular hypertrophy and myotonic electrical reactions. There was no familial history obtainable.

Angell,¹³ in the same year, reported a typical case in a German who had emigrated to this country as a boy. A brother had shot himself because, while serving in the German army, he had frequently gotten himself into difficulty because of his myotonic reaction. This had happened twenty-five years previously (i.e., in 1866) and thus before the publication of Thomsen had called attention to this difficulty for soldiers. It may be recalled that one of Thomsen's motives for revealing the family secret was for just this reason, to vindicate an affected brother and a soldier from unmerited punishment. Hence, the congenital factor is shown for the first time in the American literature. Angell would add to the diagnostic signs the marked wheal-like reaction to pin prick and delayed bleeding. The myotonic difficulty had been present since childhood, and there was definite muscular hypertrophy.

Coe,¹⁴ in 1896, briefly referred to a case seen at Dr Moyer's clinic in Chicago.

Clemesha¹⁵ reported the interesting history of a patient in whom paroxysmal attacks of loss of power had been occurring for twenty years. He first noted it at about the age of 13. The case was not one of Thomsen's disease, although recorded under this title (it was more like a familial paroxysmal palsy), as he wrote that only after "two or three hours brisk walk" could the patient abort the oncoming paralysis. At first the difficulty would show itself every three or four weeks, later months might elapse. He spoke of his being attacked at night and stated that the extremities alone were involved, save at times when he was unable to rotate the head. A family tree showing involvement of three generations is given.

The American literature contained little for seven years, when Jacoby,¹⁶ in 1898, offered a second important contribution to the subject. His first patient, a West Virginia youth of Irish parentage (presented before the New York Neurological Society in November, 1897), was apparently well until the age of 18, when, two years later after an attack of typhoid, the myotonic situation developed. All the muscles were involved, including the tongue and jaw muscles. The mechanical reactions were negative, the electrical reactions, questionable. The microscopic studies were of much interest, as bits of contracted and noncontracted muscles showed different pictures.

The absence of any hereditary history and the late development requires the use of the 'acquired' hypothesis. Dr Jacoby also presented in this study a more typical 'acquired' case and a 'transitory' case (to be compared with the case reported by Down¹⁷).

Graeme Hammond,¹⁸ at the same meeting, presented two sisters and a brother with myotonia which had developed later in life. One patient was feeble-minded. The myotonic spasms were present only in the hands and arms, and there were no electrical changes. They were presented as nontypical cases.

Lord,¹⁹ in 1900, reported the cases of two brothers and a sister with atypical forms. The brother, aged 18, first noted at 12 that he had difficulties in the thigh muscles, which would limber up after two or three movements. He would stub his toes and fall. If he sneezed, there would be an abdominal spasm. His fists would not release. Cold and dampness increased the difficulty. He had great difficulty in milking. There were large hypertrophied muscles with mechanical irritability. A brother is reported to have had the same trouble. He was not examined. A sister, aged 23, would have periodic myotonic difficulties, especially at the menstrual epoch. She was all right as soon as the flow began.

Gardiner,²⁰ in 1901, reported the case of a boy, aged 6 years, whose mother stated that during her pregnancy she had had difficulties in muscular adaptation of the myotonic type. She fell frequently. After delivery, she had no further trouble. Her child, however, had all the classic difficulties from birth. Here there was also a gradual hypertrophy of the musculature and mechanical reactions.

J. T. Jones,²¹ in 1900, reported the case of two brothers suffering from Thomsen's disease. W. M., aged 25, always in difficulty in games by reason of checking, had well developed muscles. He had trouble with all initial movements, with gradual easement on repetition. The arms and legs were worse, with mechanical and electrical reactions as described by Erb.

E. M., aged 21, had manifestations similar to his brother's, the electrical reactions being less pronounced.

Zahorsky's²² case, cited as myotonia congenita in the literature, was a case of Oppenheim's disease (myotonia congenita).

Carncross,²³ in a brief society transactions report, recited the case of a man, aged 21, who had noted the stiffening reaction at the age of 2. Marked muscular hypertrophy and great strength were present as well. Atrophy set in at the age of 17. All his muscles, including the tongue, were affected. There was a negative family history save that the mother had had some facial spasms. In the discussion, Dr F. X. Dercum referred briefly to a bricklayer who showed the myotonic reaction and Dr D. J. McCarthy to three cases that he had seen in Jolly's clinic in Berlin.

Meara,²⁴ in 1905, reported the case of a rather sickly boy, aged 10 years, who at the age of 2 noted that the stiffness in his gait increased in summer to nonconvulsive rigidity. The more sudden the motion, the greater the stiffness with later regained power. He was sensitive and emotional, he was stocky and had a squint when younger. His smile was slow, with a tendency to tapir mouth. He had a muffling speech, and there was excellent muscular development. There was an

Erb galvanic reaction There was no familial history. He came of American stock. Meara's case is of special interest in that few observations have been reported on the incidence of the disease in young children, although both Thomsen and Friis report early incidence.

Clark and Atwood,²⁵ in 1907, reported the case of a man, aged 23, of Scotch parentage, whose sister was said to have had the same difficulty since the age of 10. An older brother had similar difficulties. When at 10 he would start to run, he would fall. He recovered completely. The patient had an athletic build. The myotonic movement reaction was in the legs and arms chiefly, the face was not involved. Erb and mechanical reactions of Thomsen's disease were present.

Atwood²⁶ presented the case just noted at a meeting of the Neurological Society. In the discussion, Dr Jacoby was inclined to class it with Erb's irregular forms.

Birt's²⁷ case is of special interest, particularly as he reported his own difficulty. Birt's report stands out as a classic similar to that of Thomsen and also is to be compared with Nissen's later study. No case had been reported in the Canadian literature up to 1908, nor has been since. Birt prepared the study of his own case as an Edinburgh doctorate thesis—the full details have never been put in print, especially the myographic and similar studies. He made the diagnosis on himself as a medical student.

He had always had the difficulty. He could recall its annoyances from early childhood. At 7 it was called rheumatism. He fell frequently. He was strong and muscular early. Practically all his muscles were involved, the von Graefe sign was apparent. The mechanical and electrical reactions were typical and he had a bit of his muscle excised for examination, which showed the usual picture. Cold and emotional influences and fatigue increase the difficulty. Small doses of alcohol facilitated his motions. The family tree was typical. At the age of 68 he²⁸ is well, he still has myotonia, but no atrophies or other changes have taken place.

Rudolf,²⁹ in 1910, continued the story of Dr Birt in a reprint, with notes on the original description by Birt.

Down,¹⁷ in 1908, reported a case with negative hereditary history with the more essential features of the acquired type of the disease. A man, aged 56, a gardener, had had a probable cerebral concussion twenty years earlier, but the myotonic symptoms were of only recent happening and lasted but a year. This case can hardly be grouped with the Thomsen series.

Sedgwick,³⁰ in 1910, made a definite contribution to the presence of von Graefe's symptom, which had been known to only a few (Oppenheim). He traced this particular manifestation through a family tree with five generations. In many, the myotonia had been overlooked.

Boot,³¹ in 1913, reported typical cases in a family in which the father and mother were first cousins. The patient's mother had had the same trouble. Of three siblings in the family, two were involved with the

classic manifestations. E. H., a man, aged 21, had been involved since infancy and well noted at 5, when he fell frequently. He could never start a fight and hence was always knocked out before he could begin. In military school he had great difficulties in drill. His ciliary muscles were also involved, as was the diaphragm and his speech. The cold made him much worse.

Rosenbloom and Cohoe,³² in 1914, offered a metabolic analysis with the view of determining the nature of the calcium metabolism. The patient, G. M., an Austrian, first noted his difficulty as early as the age of 12.

W. A. Jones³³ contributed a brief note in 1915. Mrs. E. S., aged 41, whose mother was said to have been involved but whose siblings were not, recalls that as a little girl she had clumsy hands. Her tongue would be stiff as she started to talk or eat. Sometimes she could not open her jaws. At the age of 36, she had similar spastic conditions in her legs. She had the mechanical-electrical characteristics, and a bit of excised muscle showed hypertrophy of fibers and nuclei. Cold always made her worse.

Toomey,³⁴ in 1916, reported in a family of Irish parentage some intermittent cases, he saw five out of eight members in two generations. These cases were more cramplike, and the spells lasted a week or so. Up to that time Toomey reported 400 cases listed in the *Index Catalogue of the Library of the Surgeon General's Office* and the *Index Medicus*. A short bibliography of the intermittent cases is given.

Taylor³⁵ briefly discussed a sporadic case in an Italian, aged 24, with no hereditary history. Symptoms began at 10 and behaved intermittently, being worse in the morning and easing up later in the day. The patient was of an athletic type. The cranial nerves were not involved.

Frink,³⁶ in a short society note in 1917, reported the case of a school boy, aged 10 years, of Spanish parentage, with a negative family history. He always had difficulty in walking but could run well if he practiced a bit. His condition improved (?) with thymus.

Morrison,³⁷ in 1920, reported the case of a farmer, aged 34, with heavy muscles. At 10, he noted intensive rigidity. His mother had also had it but later in life was free. All his muscles were involved, and he had prodigious strength.

Rosett,³⁸ in 1922, offered, albeit in an English journal, the most thorough study of the disorder, founded on material studied in the United States. His family was originally English, and the histories of three generations were recorded. Anna H. L., the grandmother, born in Derbyshire, had the "stiff" phenomena characteristic of the disease. There were six surviving children. Three of these, Herbert L., aged 33, Louise W., aged 35, and Sarah E. M., had myotonia congenita. Two other brothers and a sister were free from the muscular disturbance but had mental disturbances. The oldest girl, Laura C., was nervous and had depressed and irritable

attacks "just like her mother." A brother, W L, Jr, had short attacks of "nervousness," in which he was "out of his mind." These attacks were of short duration. Harry L had general "nervousness," had been very despondent at times, and had attempted suicide.

The third generation was represented by ten children. Of these, Rosett was able to examine three who had myotonia congenita. Lorraine L, aged 7, was the daughter of Herbert L. Mildred, the daughter of Louise W, had a typical myotonia. The report concerning Mildred was full and detailed. Mabel W had typical Thomsen's disease. It was noticed that when she sneezed her eyelids would remain closed. Nathalie W, aged only 3 years and 6 months, showed this sneezing reaction but otherwise no myotonia.

Rosett entered into a discussion of the mechanism of the muscular action and laid considerable stress on what is here called psychic or emotional stimulus. The "resistance of unrelaxed antagonists" seems the most consistent situation. He weighed the hypothesis that the frequently found atrophy might be interpreted as an overaction of the unrelaxed antagonists. The participation of the facial muscles seemed to him to negate this idea. A "neuritic" element seemed to be present in some patients, pain and diminution of reflexes being partial evidence in this direction.

Rosett then discussed fully the heredity of the large musculature. A sublethal inherited factor was posited as behind the frequently found atrophy.

This sublethal factor may be represented in different structural components of the disorder. Sometimes the pseudohypertrophic muscles, sometimes the neural elements, either central or peripheral. If central, the psychotic trend is thought to be explained.

The fear of ridicule and the tendency on the part of involved members to conceal their infirmity was touched on by the author as contributing to the difficulty in learning more about this disorder.

A B Jones,³⁹ in 1927, presented a brief clinical note.

Barker,⁴⁰ in 1930, presented at a clinical lecture a housewife, aged 43, of Italian origin, whose one sister and a cousin on the father's side were also involved. Two children, aged 16 and 6, were free. The patient noted that at 10 she easily fell over when her brother pushed her. She had the typical myotonic reactions in the hands, muscular hypertrophies, and mechanical and electrical reactions.

CLINICAL HISTORY OF AUTHOR'S CASE

History.—N B was 28 years of age when I first learned that he had such a difficulty. He was of Dutch ancestry. His parents had moved to England, where he was born. He came to the United States as an infant. His parents, so far as he knew, were not closely related. Only his mother was alive when I first met him; his father had died at the age of 63 of an apoplectic stroke. The father's mother's family name was Arions; the mother's Mcurs and her mother he thinks was a de Boer. The mother died at the age of 67 of a heart disorder. She also had myotonia. The family tree will be discussed later.

The patient states that he has had his difficulty ever since he can remember. It was a special source of chagrin to him as a boy of 6, 7 or 8 years when the kids were having a bonfire and suddenly a policeman appeared and the familiar cry of "Cheese, it the cop!" was called. He was always the goat. He would start to run, his muscles would stiffen up, and he would fall on his nose and get caught. In playing baseball,

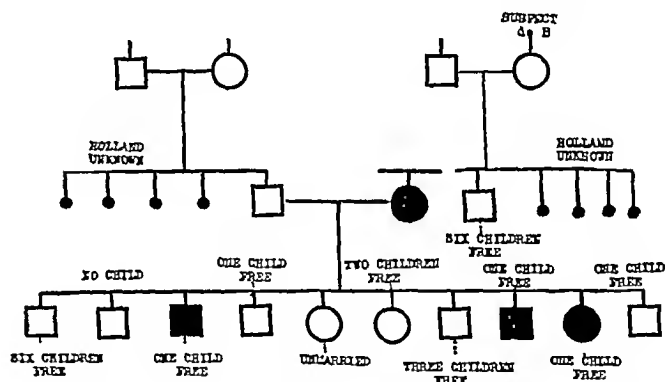

unless he danced around the plate and swung his bat freely, he could not start to run. It has been that way ever since.

If there are two steps on a trolley car it is all right, but if he must go up more than two steps he is in trouble. The legs stiffen; there is no spasm, they are just stiff. He cannot lift either foot high enough to make the next step, and, if he does not wait and make the third slowly, and then the fourth and then with increasing facility the others, he will stumble and fall. When he gets started he is as limber as any one.

There are no voluntary muscles of the body that seem to have escaped. The familiar closing of the fist experiment is classic, walking is the same. In closing his eyelids he has the same difficulty. It is a strange symptom at times that when talking and he yawns, his tongue stiffens and he is unable to talk for a moment. He dare not dive into the water for a swim but can go in gradually from a dock, limber up and be all right.

One experience stands out with vividness because of its annoying consequences. In 1928, while riding in the Hudson Tunnel to New Jersey, he became engrossed in his newspaper. The Journal Square station was reached and he suddenly realized that he had to change cars there. He arose quickly and succeeded in getting to the opening of the subway train, when his legs got stiff, he barely managed to get out and fell back against the side of the car, now in motion. He had presence of mind enough to shove himself away from the moving train and fell flat on the platform.

Examination.—He has the usual well developed, almost hypertrophic musculature. He is well built, about 5 feet

The family tree. The squares in the chart indicate males, the circles females. The solid black figures show involvement with Thomsen's disease.

7½ inches (170 cm) tall, and weighs about 140 pounds (63.5 Kg).

A neurologic examination by Dr Ziegler revealed the following in 1932:

The cranial nerves show no marked neurologic anomalies.

There are no anomalies of smell or of sight. He wears glasses for a mild degree of myopia. The fundi are normal.

Ocular movements are free in all directions. He has not been aware of any stiffening in these muscular movements. The pupils are equal and react to light and in accommodation freely. There is slight nonsustained horizontal nystagmus. The von Graefe sign is present when he closes his eyes.

As already noted, the tongue and jaw muscles are often involved in the myotonic fixation, but there are no gross disturbances of the fifth or the seventh nerve in motility or sensation. There is slight facial asymmetry.

The muscles of the arms are well developed but not markedly hypertrophied. There are no anesthesias nor palsies. Mechanical tapping of the muscles produces the well known local bulging of the muscles with slow subsidence. This is quite marked on tapping of the thenar eminence. The characteristic stiff holding reaction is present in all the voluntary movements. Fist closing, hand shaking, quick jerking—as in fishing—are impossible. There is even diaphragmatic holding when the patient sneezes.

To the touch there is no hardness and no increased tonus save on the initial movements. There is no adiadokokinesis after limbering up, no ataxia, sensory changes nor difficulties

⁴⁰ Barker, L. F. Case of Myotonia Congenita. M. Clin. North America 14: 12 (July) 1930.

in skilled movements. The two sides are equal in strength. The skin and tendon reflexes show no variations. There are no pyramidal or extrapyramidal tract signs.

In the trunk the same myotonic stiffness shows itself in any large quick movements. The abdominal reflexes are present and equal. The cremasteric reflex is more of a dartos than a cremasteric reflex. There is no bladder or bowel disturbance. The genitals are not large, ejaculation is satisfactory. An electrocardiogram showed no changes in the heart muscle in timing or rhythm.

Examination of the lower extremities gives the same results as of the upper. The gastrocnemius is well developed and mechanical excitation shows definite myotonic reactions. There are no Babinski, Chaddock or sensory anomalies of any kind.

THE FAMILY TREE

Only one of the members of this group has come under personal observation thus far. The details are scanty. The patient recollects but little of his childhood. Both his father and his mother died when he was comparatively young, he is uncertain as to details.

His father's father married three or four times. He had children by all marriages. His mother's father married twice, maybe three times. Most of the descendants live in Holland.

The mother (Meurs) is the first of the family of whom to the present time any information is known. She had Thomsen's disease and died of heart disease at the age of 67. Her mother's name was de Boer and it is through this branch that we hope to trace the de Boer family of Wertheim Salomonson's case history. The father died at the age of 68. Of the mother's sisters and brothers the patient knows only remotely that there are four living in Holland, one brother with six children, all of whom are said to be free of the disorder.

Among the patient's own siblings—there are ten children, seven boys and three girls—the third and eighth (males) and ninth (female) are involved. The patient is the eighth child born. Of these may be stated in order as of September, 1929:

1 Jacob B, 54 years of age in 1927, suffers from some form of heart trouble. He has six children, one girl and five boys, all of whom are free. The girl has a heart murmur.

2 Peter B died of cirrhosis of the liver at 53. He had married but had no children. Physically he resembled the patient but was a little taller. He was always ailing. He had had catarrh, asthma and malaria. He had been a printer in the government service at Washington, D. C. He had a complication of complaints and became emaciated. Appendicitis was suspected but was not found at operation.

3 Cornelius B, aged 50, like the patient, always had "cramps" in his muscles. He is a machinist, married and has two children, neither of whom has any muscular trouble.

4 John B had a tumor of the kidney and died at the age of 53. He was darkly pigmented. He had one child, who was not involved.

5 Johanna B died at the age of 34, in 1914, of some kidney disorder.

6 Emma B was always sickly, thin and darkly pigmented. Her heart was enlarged. She was an invalid and died at the age of 49. She had two children, who are living and well.

7 Seymour B is living and well. He is married and has three children, one boy and two girls. None of them have Thomsen's disease.

8 Nicholas B, the patient, has one child, who is not involved.

9 Anna B had Thomsen's disease when young but has improved since growing up. She married, is well and has one daughter.

10 Harold B, aged 33, has had kidney stones. At the present time he is well. He has one daughter.

64 West Fifty-Sixth Street

THE SPECIFIC SERUM TREATMENT OF PNEUMOCOCCUS TYPE II PNEUMONIA

MAXWELL FINLAND, M.D.
AND

WHEELAN D. SUTLIFF, M.D.
BOSTON

The clinical entity "lobar pneumonia" is gradually coming to be recognized as comprising a group of specific infectious diseases.¹ This is due primarily to the interest aroused by the serologic classification of the pneumococci and the elaboration of specific therapeutic serums against two of the most frequent of these types, namely, types I and II.

The beneficial effects of specific antipneumococcic serum in the treatment of pneumonia due to the type I pneumococcus have been repeatedly demonstrated. In pneumonia due to this type, the death rate has been reduced by one half,² and rapid symptomatic improvement has been observed³ in cases treated early in the disease.

The type II pneumococcus occupies an important place in the etiology of lobar pneumonia. It causes between 13⁴ and 23⁵ per cent of all pneumococcic pneumonias with a mortality, in non-serum treated cases, of from 30^{2b} to 46⁵ per cent. It is a remarkably infrequent inhabitant of the normal respiratory tract.⁶ Gundel⁷ has recently emphasized its significance in relation to the pathogenesis of primary lobar pneumonia. At the Boston City Hospital the typing of large numbers of strains of pneumococci from various sources has confirmed this relation. During the past three years type II pneumococci were recovered in one or more specimens from 166 different patients. A study of all these cases revealed that lobar pneumonia was present in 152, or 91.6 per cent, of the patients. Bronchopneumonia was present in five patients, in two of these it occurred as a complication of measles, in two others it followed surgical operations, and in the fifth patient there was a lung abscess and the pneumonia was a terminal event. In only nine, or 5.4 per cent of the cases, was pneumonic consolidation definitely absent.

The reported results from specific serum therapy in pneumonias due to the type II pneumococcus have not

From the Thorndike Memorial Laboratory, Second and Fourth medical services (Harvard) of the Boston City Hospital and the Department of Medicine of the Harvard Medical School.

This study received financial aid, in part, from the William W. Wellington Fund of the Harvard Medical School and, in part, from a grant given in memory of Francis W. Peabody by the Ella Sachs Plotz Foundation.

The authors are indebted to those whose assistance and cooperation made this study possible, namely, Drs. J. G. Kelley, J. M. Bethea, T. N. Hunnicut, J. W. Parsons, H. J. Stanford, C. W. Steele and C. E. Welch, and Mrs. Mary Truesdale, Miss Beatrice Tyndall and Miss Mary Carroll. The staffs of the Medical and the Pathologic services also cooperated.

been as uniform or as convincing as those obtained in type I cases Cecil and Plummer,⁸ in reviewing five years' experience with Felton's serum at Bellevue Hospital, did not find a striking difference between the mortality in type II cases treated with specific antibodies and in alternate untreated control cases In the year 1930-1931, however, in a carefully alternated series of cases admitted to the hospital within seventy-two hours of the onset of type II pneumonia, these authors report three deaths among twenty-one recipients of Felton's serum, a mortality of 14 per cent, as compared with thirteen deaths among twenty controls, a mortality of 65 per cent Baldwin,⁹ at the New York Hospital, found the death rate in type II cases treated with Felton's serum about one-half that in alternate non-serum treated controls In a previous report from the Boston City Hospital^{2c} and one from the Harlem Hospital,^{2b} the mortality in type II cases was found to be favorably influenced by Felton's serum, but the differences between treated cases and controls were not striking

Both Cecil and Plummer and Baldwin failed to observe the rapid clinical improvement in type II cases treated with serum that is so constantly observed in specifically treated type I cases They did, however, gain the impression that the former were definitely less toxic after administration of the specific antibodies On the other hand, Armstrong and Johnson,⁹ at St Bartholomew's Hospital, on the basis of careful clinical observations in a small group of cases, failed to note any difference between the character of the response in the type I and the type II specifically treated cases

During the past three years at the Boston City Hospital a special study has been made of the efficacy of concentrated pneumococcic antibodies (Felton) in the treatment of pneumonias due to the type II pneumococcus Large doses of serums, especially selected for their high titer of type II antibodies, were administered within short intervals of time with the object of studying the effect of such treatment on the clinical course of the disease In view of the conflicting evidence and of the prevailing skepticism among many writers, a report of the results of this study may be of interest

SELECTION OF CASES

In the earlier part of this work serum was given in every alternate case of clinical lobar pneumonia from which type II pneumococcus was obtained In the latter part, serum was given only to patients admitted to the hospital within ninety-six hours of the onset of their disease In a number of early cases, however, there was failure to administer serum for various reasons They were mainly patients in whom the clinical or bacteriologic diagnosis was delayed and those under the care of physicians who preferred not to use antipneumococcic serums These cases and the ones admitted late in the disease have been studied in a similar manner as those in which serum was given The results in these cases are presented with the distinct understanding that they do not represent controls They are, however, of interest as representing contemporaneous cases in the same hospital, with the same general care and treatment, except for specific serum therapy

SERUM, SOURCE AND POTENCY

The serum used in this study was obtained from horses immunized against type I and II pneumococci and was concentrated according to the method of Felton¹⁰ It was concentrated and supplied, for the most part, by Dr Felton of the Department of Preventive Medicine and Hygiene of Harvard Medical School Occasional patients received, in whole or in part, bivalent (types I and II) serum prepared and concentrated in the Antitoxin and Vaccine Laboratory of the Massachusetts Department of Public Health and supplied through the courtesy of Dr Benjamin White During the last few months of this study the greater part of the serum was supplied through the Lederle Laboratories The serums were especially chosen because of their high content of type II antibodies Most of the lots ranged in potency from 2,000 to 5,000 Felton units,¹¹ the average for all the serums used being 3,000 units of type II antibodies per cubic centimeter All serum was given intravenously with the usual precautions and in a manner similar to that previously described in connection with type I cases³

DOSAGE

There is reason to believe that larger amounts of specific antibodies are necessary to obtain curative effects in type II cases than are required in pneumonias due to the type I pneumococcus, presumably because of the larger amount of specific soluble substance excreted by the former In type I cases it was early recognized and has been frequently reiterated by those having experience with antipneumococcic serum therapy that large doses of potent serums are essential for effective curative results This has been observed especially in severe cases presenting bacteremia In severe type II cases, Cole¹² was unable to maintain a balance of specific antibodies in the blood, using a serum of rather low potency The more recent work of Park and Cooper¹³ indicates that large doses of highly potent serums are necessary, in many cases, to establish such a balance, and that in some instances it is difficult, even then, to maintain Thus, Cecil and Plummer⁸ attempted to "administer from 100,000 to 200,000 units (from 40 to 100 cc) [of concentrated antibody] during each twenty-four hour period until the patient showed definite signs of recovery or until it was evident that the serum was exerting no influence whatever on the disease" Park, Bullowa and Rosenbluth^{2b} noted that it is important to start treatment early in persons with type II pneumonia and to give them more antibody than those with type I and that in late severe type II cases it may be impossible to give enough

In the cases here presented an attempt was made to introduce a large amount of antibody within a short space of time Most of the cases were given a first dose of 5, a second dose of 25 and then three or four doses of 40 or 50 cc at intervals of two hours Further doses were then given after a lapse of from eight to twelve or more hours if the clinical response was not entirely satisfactory Some variations were made when

reactions occurred or whenever the condition of the patient warranted. On the average, a total of 175 cc, containing approximately 540,000 units of type II antibodies, was given in six doses within twenty-four hours after treatment was instituted. Four patients received more than 300 cc, the largest dose being 475 cc, and five patients received less than 50 cc. In about one half of the cases the full dose of serum was given within twelve hours of the time the first dose was given. In fatal cases admitted within ninety-six hours of the onset of the disease, excluding one patient in whom serum was discontinued after a single dose of 5 cc, 239 cc (containing approximately 840,000 units of type II antibody) was given, on the average, in eight doses over a period of twenty-nine hours.

TYPING

In a majority of these cases the type was determined within five hours after a proper specimen was obtained. This was usually determined from the sputum by the Sabin¹⁴ method, but occasionally direct precipitation of the urine¹⁵ or of the sputum¹⁶ was used. Atypical strains were, in most instances, eliminated by direct agglutination with specific antisera prepared against these strains,¹⁷ especially the type V, corresponding to the one formerly recognized as type IIa. Routine mouse typing¹⁸ of the same sputum was always used as a check and, in most instances, additional specimens were likewise typed. Pneumococci obtained from the blood and from other sources were all typed.

In the present group of cases, the results of the typing were remarkably uniform. In only 5 of 135 cases (4 per cent) did the routine typing of the initial sputum fail to reveal the correct serologic group when subsequent specimens yielded type II pneumococci. From four of these initial sputums no organisms could be recovered from the mouse and from the fifth only influenza bacilli were recovered. There was only a single instance in which a Sabin test at the end of four hours was interpreted as showing agglutination in type I antiserum in a sputum which later proved to be a type II and another instance, to be mentioned later, in which pneumococci agglutinating in type IV antiserum (Cooper) were isolated from later sputums. With these exceptions, whenever pneumococci were obtained from more than one source in the same patient they all checked in regard to type.

EVALUATION OF THE RESULTS OF SERUM THERAPY

Effect on Mortality—In evaluating the therapeutic efficacy of any agent in a disease as variable in its course and outcome as lobar pneumonia, it is hazardous to draw final conclusions except after a careful study of groups of comparable treated and untreated cases. Due regard must be given to those factors which have an obvious and gross influence on the prognosis and course of this disease. The most important of these factors may be reviewed briefly.

The first is the etiologic agent and, particularly when the pneumococcus is the invader, its serologic type. This factor has been repeatedly emphasized by those who have been in a position to make bacteriologic and serologic studies in addition to clinical observations.¹ The scope of the present paper is clearly limited in this respect.

A second factor, the importance of which has long been recognized, is the age of the patient. A steady rise in mortality with increasing age has been clearly demonstrated at Bellevue Hospital by Cecil, Baldwin and Larsen¹⁹ in a large series of cases of pneumonia due to all types. This appears just as strikingly from the data of the Royal Infirmary in Glasgow²⁰ and from the Boston City Hospital.²¹

A third consideration is that of the presence or absence of bacteremia. Many observers have noted the striking difference in mortality between patients with and those without bacteremia. The former have been found, in non-serum treated cases, to have a death rate from three to as much as ten or more times that of cases due to the same type of pneumococcus but presenting negative blood cultures.²

Variations in mortality from year to year have been noted repeatedly by the various writers, even in pneumonias of the same type and in the same hospital. An outstanding recent acknowledgment of the fallacy of drawing conclusions from a comparison of cases chosen in different years appears in a recent report on the dextrose treatment of pneumonia.²²

The duration of the disease at the time a therapeutic agent is administered is probably of importance in evaluating its efficacy. This has been demonstrated by Goodner²³ in experiments on the dermal pneumonia in rabbits. In several of the reports on serum therapy already mentioned, and in Locke's²⁴ study of the serum treatment of type I cases, considerable significance is attached to the early administration of serum. Other observers, notably Cole²⁵ in type I cases and Baldwin,⁸ have not found this a factor of great importance.

Finally, the presence of complicating factors, notably alcoholism and other acute or chronic diseases, may have a decided influence on the outcome.

In some of the therapeutic experiments with serum in the treatment of pneumonia, an attempt was made to balance the errors arising from these and other factors by obtaining large numbers of cases and applying some method of alternation. In the Harlem Hospital series,²⁰ a statistical weighting of these factors was utilized in addition. In the present series, except in the earlier cases, alternation was not attempted, since the primary object of this study was to learn the effect of serum on the clinical course of the disease. Reference has been made to the manner in which the type II cases were selected for specific treatment. The mortality in these cases has been analyzed with respect to the more important factors discussed in this paper and a similar

* Two patients subsequently had positive blood culture one died

total of 142 cases, were studied. The cases in which death occurred within twenty-four hours of the time of admission to the hospital (one serum treated and five non-serum treated) and those whose type was first obtained at autopsy (eight non-serum treated cases) are excluded from the mortality figures. One case in which serum treatment was discontinued after a single dose of 5 cc and in which death ensued nine days later is likewise excluded. Of the remaining 127 cases, Felton's serum was given in 46 and not given in 81. There were nine deaths among the former, a mortality of 20 per cent, and thirty-two deaths among the latter, a mortality of 40 per cent.

The influence of the various factors mentioned on the mortality in the treated and untreated cases are summarized in table 1. Briefly, the mortality in the treated cases has been consistently lower than in those not treated. There were no deaths among the treated cases under the age of 40 years and the results were most favorable in the cases treated before the end of the fourth day and in those having negative blood cultures. The complicating factors present in the fatal cases will be mentioned later. Among the cases ending in recovery, alcoholism was present in ten serum treated cases and in nine cases not treated. There was one cardiac patient and one patient with tuberculosis among the treated patients who recovered, and, among those not treated, one with cardiac disease, two with tuberculosis and one with diabetes survived. In general the incidence of complicating disease was comparable in these groups except for a higher percentage of alcoholic patients among the serum recipients.

Effect on Bacteremia.—The mortality in relation to the result of the first blood culture is given, for both the treated and the untreated cases, in the lower portion of table 1. The number of bacteremic cases treated is not very large. The course of the bacteremia in these

and in the untreated cases is, however, of interest. Among the untreated cases whose first blood cultures were negative, pneumococci were recovered from the blood on later occasions in five (one only at autopsy), and four of these ended fatally. No such phenomenon was observed among the treated cases. The course of the bacteremia in the fatal cases is discussed later. Among the recovered cases, the largest number of colonies grown from 1 cc of blood in an untreated case was 250 and in a treated case, 360 (before treatment). In the former patient, empyema and purulent conjunctivitis subsequently developed, the latter patient subsequently had a positive culture after only 5 cc of serum, but numerous other cultures were negative, although the fever persisted for ninety-six hours, during which time the patient was given repeated doses of serum.

SUMMARY OF FATAL CASES

In general, all the fatal treated cases, with one exception, were either treated late or had important factors contributing to the outcome. On the other hand, most of the untreated cases ending fatally had no such contributing factors and death in them was due to the pneumococcal infection. It is of interest to summarize some of the significant observations in the fatal cases (table 2).

All of the nine serum treated patients who died were over 40 years of age, and only three were under 50. Two of the patients died before the end of the fifth day, and the disease lasted as long as ten days in only one case. Death occurred in two instances within eight hours after serum treatment was begun, and in another within sixteen hours. A history of chronic illness suggesting pulmonary tuberculosis was present in three cases, and meningeal involvement (with no pneumococci found in cloudy fluid from the cisterna magna after death) was present in one of these. Auricular

* Including one from heart's blood

† Two treated and two untreated were negative at autopsy

fibrillation with marked pulse deficit was present in two cases before serum was given. There were seven patients with chronic alcoholism in this group, four of these were acutely intoxicated on admission and in one delirium tremens developed. In one of the acute alcoholic patients the pneumonia followed soon after severe injuries to the head, chest and internal organs, resulting from an automobile accident. Bilateral lung involvement was present in three cases and one entire

lung was involved in a fourth case before serum was given. The blood culture was positive before serum treatment in six instances, but specimens taken after serum treatment were negative in four of these cases (the heart's blood at autopsy in two of the latter). In one of the remaining cases the number of organisms recovered from the blood was reduced from 4,000 to

9 per cubic centimeter after serum was given, and in the other case the blood invasion increased in spite of intensive treatment (This was the injured alcoholic patient). One patient was treated with small doses because of the appearance of urticaria immediately following one of the injections. The blood culture, which was positive before the first dose, became negative and stayed so for three days after 75 cc of serum had been given. On the fourth day pneumococci were again

patients, one of whom had arthritis in addition, and in one case there was a subcutaneous abscess from which type II pneumococci were recovered. Extension of the pulmonary consolidation was definitely demonstrated in only two instances.

DURATION OF THE DISEASE

While a definite reduction in mortality is the ultimate aim of specific therapeutic serum, it is desirable to have some method of gauging efficacy in the individual patient. To the physician confronted with one case, some obvious effect on the course of the disease is greatly to be desired. To measure such an effect accurately in the disease with which we are dealing is not possible since no single measurable factor has been recognized which can be taken as an index to the course and severity of the infection in every case. It is feasible, however, to select those signs and symptoms commonly recognized as being indicative of the presence and activity of the acute disease and compare the duration of these signs and symptoms in the cases treated with serum and in those not treated with serum. A simple method of comparing cases in this respect has been previously described and applied to a series of type I cases,⁸ and the same general method was applied to the present cases.

Only cases that were admitted to the hospital within ninety-six hours of the onset of the disease and in which recovery had occurred were analyzed in this manner. The cases were studied first with respect to the duration of the disease to the time when the temperature first permanently dropped below 101 F and, secondly, with respect to the time when all symptoms of the acute disease abated and the temperature permanently remained below 100 F.

In chart 1 all the cases of type II pneumonia admitted to the hospital within ninety-six hours of onset and ending in recovery without febrile complications are charted according to the duration of the disease at the time of admission to the hospital and the duration from that time to the first permanent drop in temperature below 101 F. Each dot represents one serum treated case and each cross represents one untreated case. It will be seen at a glance that most of the dots appear below

Chart 2—Duration of symptoms in the hospital. The duration at entry is charted against the duration, in hours, from admission to the disappearance of all symptoms of the acute disease and all fever of 100 or higher.

Chart 1—Duration of fever in the hospital. The duration at entry, in hours, is charted against the time from admission to the first permanent drop in temperature below 101 F. In this chart and in chart 2, each dot represents one serum treated case, and each cross one untreated case.

recovered from the blood, which was again effectively sterilized by the administration of 30 cc in three doses. In no case did bacteremia develop after serum treatment was begun, and extensions of the pneumonic process were not made out. Serum was first begun before the fourth day in only four cases, one of these patients being the man with the injuries and another the one who received the small doses. One case showed multiple abscesses in the lung at autopsy.

Among the thirty-two patients who died without receiving serum, nine were under 40 years of age and twenty-two (two thirds of the patients) were under 50. Four died before the end of the fifth day of the disease and ten died on the tenth day or later. Only six died on the second day after admission to the hospital, whereas twenty lived three days or more after entry. Chronic bronchitis was present in three cases, diabetes in one, and hypertension with auricular fibrillation in one. There were twelve patients with chronic alcoholism, eight of these were acutely intoxicated on admission and in three of the latter delirium tremens developed. Bilateral lung involvement was present in four and unilateral involvement of more than one lobe was present in five others. The first blood culture taken was positive in twenty of the cases and an increase in the extent of the bacterial invasion was demonstrated in five of these, whereas in three others death ensued in spite of the fact that no pneumococci could subsequently be isolated from the blood (even from the heart at autopsy in two of these cases). In four additional cases pneumococci were recovered from the blood only on second or later attempt (at autopsy in one instance). Pneumococcal meningitis was found at autopsy in one case, empyema in one, and hydro-nephrosis in one. Pericarditis was suspected in two

the horizontal line representing forty-eight hours, and most of the crosses appear rather widely scattered above this line. Specifically, twenty-eight (85 per cent) of the thirty-three recipients of serum who recovered had a permanent drop in temperature below 101 F within forty-eight hours after admission to the hospital,

whereas the same was true in only five (22 per cent) of the twenty-three untreated patients who recovered. The average delay from admission to the time serum was given was thirteen hours.

The duration, after admission to the hospital, of all the symptoms of the acute disease, including fever of 100 F or higher, is presented in the same manner in

Chart 3—Duration of the disease in serum treated cases. In charts 3 and 4 each bar represents one patient. The distance of the bar from the base line represents the duration of the disease before entry; the hatched portion the time from admission to the time of serum administration; the solid portion the time to the first permanent drop in temperature below 101 F, and the light portion the time until all symptoms and fever, of 100 F or higher, disappeared. Only cases in which recovery occurred without febrile complications are shown.

chart 2. From this it will be seen that eighteen (55 per cent) of the recovered serum recipients who were admitted to the hospital within ninety-six hours of onset were asymptomatic and afebrile within forty-eight hours after entry and twenty-six (79 per cent) were free of symptoms within ninety-six hours, whereas only two (87 per cent) of the early untreated cases were symptom free within forty-eight hours and eight (35 per cent) within ninety-six hours. The contrast between the duration of fever and symptoms in the treated and untreated cases appears strikingly from a comparison of charts 3 and 4, in which the course of the disease in each of the cases is represented diagrammatically.

EXTENSIONS

The effect of serum therapy on the process in the lung is another important consideration. It is to be expected that a specific agent, while it may not influence the evolution of the process already developed, may act in some way to limit its spread. The clinical and roentgenographic observations were utilized to determine whether extension of the consolidation occurred. Extension was made out in only one of the treated cases in which recovery occurred.

This was a patient from whose blood type II pneumococci were recovered before serum was begun and after 5 cc had been given. He was found by physical and roentgen examination, to have an extension to the opposite hilar region on the day treatment was begun. Many subsequent blood cultures were negative. The sputum on the first two days showed type II pneumococci. Three days later type II pneumococci could no longer be isolated from his sputum, which continued to be tenacious and brown, but pneumococci agglutinating specifically in type IV antiserum (Cooper) were isolated on third and subsequent examinations. The

process did not extend far beyond the hilar region, but the course of the fever was somewhat protracted and the patient recovered. It was thought that the extension may have been due to the type IV organism.

Extensions were made out in six untreated patients who recovered. In three of these patients the opposite lung became involved, and in the others the extension was to previously unaffected lobes on the same side. Two of these patients died.

COMPLICATIONS

Febrile complications developed in two of the serum treated cases in which recovery took place. In one there was an acute otitis media and in the other a hemolytic streptococcus empyema, otitis media, and bacteremia and erysipelas of the chest wall. In the latter, recovery occurred after a protracted illness and surgical treatment. Sterile pleural effusions, not associated with fever, were present in two other cases.

Among the untreated patients who recovered, one had empyema and conjunctivitis, and type II pneumococci were obtained from both the pleura and the eye. Two patients had otitis media, a third had extensive furunculosis, and one had a sterile pleural effusion.

SERUM REACTIONS AND SERUM SICKNESS

The reactions following serum administration may be divided into three groups: (1) those occurring during or immediately after the injection, (2) thermal reactions and (3) serum sickness. Their occurrence in these cases may be briefly summarized.

Immediate Reactions—A slight or moderate increase in dyspnea was experienced by several patients, with wheezing and cyanosis in two instances. Flushing and elevation of the pulse rate for a few minutes frequently followed injections. Nausea was experienced by ten, with vomiting in four of these. Urticaria occurred during injections in six patients and mild chills were experienced by two persons immediately following one of the injections.

Thermal Reactions—A mild chill, from fifteen to ninety minutes after an injection, occurred in fourteen patients and was repeated one or two times in five of them. The greatest increase in temperature following a chill was 3 degrees Fahrenheit (to 105).

Serum Sickness

—This was present in fifteen of the thirty-seven surviving patients and was mild in all of them. The average dose was identical in treated cases in which serum sickness was present and in those in which it was not. The disease was manifested by urticaria in eleven cases, in five of these it was associated with arthralgia, in one with adenopathy and in two with both arthralgia and adenopathy. Arthralgia was present alone in three cases and along with adenopathy in one case. Fever was present in all the

Chart 4—Duration of the disease in untreated cases.

cases except four of those presenting urticaria. Two patients each had two distinct bouts of serum sickness about three days apart.

COMMENT

The data presented here indicate that a definite beneficial effect may be obtained from specific serum treatment in cases of lobar pneumonia due to type II pneumococcus. This benefit has been demonstrated in diverse ways by comparing cases treated with serum with a similar group of simultaneous, though not alternated, cases not treated with serum. In the specifically treated cases the mortality is lower, fever and other symptoms of the acute disease subside rapidly, the pneumonic consolidation is limited and bacteremia, when present, usually disappears rapidly and permanently or, when absent, does not appear after serum administration.

The favorable results in these cases were, in our opinion, due to at least three important factors, namely, early treatment, the use of large doses of potent serums, and persistence in the treatment of severe cases. That patients treated early have a low mortality and are rapidly relieved of their symptoms appears clearly from the foregoing data. Whether similar results can be obtained in cases treated late cannot be deduced from the results in these cases. It may be possible to obtain good results when the lesion is not extensive and the extrapulmonary damage is not great. When the infection continues to progress, however, the amounts of antibody necessary to obtain these results may not be practical, at least with the materials at present available.

In mild cases not presenting bacteremia, small doses may be sufficient. Thus, it has been possible to establish and maintain a balance of antibodies in the blood of many such patients even with serum of low potency¹² and with small doses of Felton's serum²⁷. In severe cases, especially in those presenting bacteremia, the experience of many writers has been that large doses of potent serums are necessary and that relapse in the bacteremia may occur and the disease progress if treatment is discontinued too soon or if insufficient amounts have been given. This was clearly shown in one of the cases mentioned.

The question may be asked whether the beneficial effects here observed may not be the nonspecific response to the protein administered. This is not likely, as no response has been noted from large doses of serum of low antibody content. In type I cases, it has been possible to demonstrate this specificity by a direct comparison in different patients and in the same patient of the response to serum containing antibodies with that following the injection of similar serum containing no specific antibodies.²⁸

SUMMARY

In a group of forty-six cases of pneumonia due to the type II pneumococcus and treated with specific antibodies, the death rate was considerably lowered and a rapid amelioration of fever and symptoms was observed in comparison with contemporaneous non-serum treated and comparable cases. These beneficial effects were obtained by early treatment with large doses of potent specific antisera, and by persistence in treatment in severe cases.

MINIMUM COST DIETARIES FOR DIABETIC PATIENTS

WILLIAM A. GROAT, M.D.
AND

MARCIA I. ROSBROOK, B.S.
SYRACUSE, N. Y.

Late in 1931, like many other communities, the city of Syracuse was confronted by the problem of feeding an increased number of indigents at a time when the municipal income was decreasing. It became imperative that economies be effected. It was equally important not to undernourish the recipients or to supply an imbalanced diet. At a conference of the

TABLE 1—Syracuse City Diet A—A General Welfare Dietary for One Adult for One Week

Item	Amount
Bread	2 loaves
Evaporated milk, tall can	3 cans
Potatoes	3 lbs
Eggs	4 eggs
Tomatoes, no. 2 can	1 can
Butter	1 1/2 lb
Granulated sugar	1 1/2 lb
Brown sugar	1 lb
Molasses, no. 1 1/2 can, dark	1 can
Choice of salmon, sardines, T. S., mackerel, codfish or other dried fish	1 can or 1/2 lb
Choice of tea, coffee, cocoa	1/2 lb
Choice of whole grain cereal, rolled oats, corn meal, tapoca, rice, pearl barley, macaroni, spaghetti, flour	1 lb
Choice of prunes, apricots, apples	1 1/2 lb
Choice of dried peas and beans	1 1/2 lb
Choice of beets, cabbage, carrots, onions	2 lbs
Choice of peanut butter, lard, salt pork	1 1/2 lb
Choice of beef, lamb or other inexpensive meats	1 lb
Salt, soda, pepper, baking powder, dry mustard, vinegar, yeast (small amounts as needed)	
Cottonseed oil may be substituted for lard, salt pork, or peanut butter at equal cost	
Average yield daily	carbohydrate, 360; protein, 78; fat, 95; calories, 2,600

Diabetic Dietary 6 Diabetic dietary 1, less 1 loaf of bread and 1 lb of potatoes, plus 1/2 lb of butter	\$1.21	138	73	138	2,100
Diabetic Dietary 7 Diabetic dietary 1 less 1 loaf of bread and 2 lbs of potatoes, plus 1/2 lb of butter	\$1.20	127	72	178	2,050

department of public welfare and the department of public health with the mayor's advisory committee on public health (a committee provided for by the charter of the city of Syracuse and appointed by the mayor from a panel selected by the Syracuse Academy of Medicine), it was decided to request the Public Health Committee of the Syracuse Academy

From the Third Medical Service, and the Department of Dietetics, Syracuse Memorial Hospital.

of Medicine to collaborate with a representative group of hospital dietitians and formulate a dietary on a minimum cost basis which would fulfil the requirements of balance, vitamins, reasonable palatability and total calories. The invitation was accepted and such a dietary was devised. A dietitian was attached to the welfare department to make the readjustments and other modifications that from time to time changing conditions might require. The city administration then discontinued the commonly used, wasteful and much abused grocery order system and established this limited choice dietary in all relief work. A method of purchase through the local grocers' association at a minimum

TABLE 3—Yield in Household Measure of Basic Diabetic Dietary 1

Bread	2 slices at each meal
Evaporated milk	Scant $\frac{1}{2}$ can daily

One-fourth pound of lard used throughout the week for cooking	
One egg used during the week in cooking	
Tea and coffee daily	

scale of profit was adopted in preference to the warehouse method used in some other communities.

This dietary has received considerable publicity as the 'Syracuse Diet' and has been accepted by other communities and approved by state agencies. It has worked successfully for our city throughout the year. The saving to the city has been estimated as approximately \$250,000. Careful check by the department of health has revealed no nutritional defects.

The dietary is varied for seasonal changes in order to take advantage of market conditions and for racial and religious habits. Children get fresh milk daily and cod liver oil and oranges during the winter, the sick get the special foods needed. A representative outline of foods furnished one adult weekly, known as City Diet A, is given in table 1.

The cost of diet A during November, 1932, was \$1.18 per person, weekly.

There are, of course, a number of diabetic patients on the city welfare list. Medical supervision and insulin are provided them through various agencies. As a

further economy, diabetic dietaries have been built out of city diet A and are tabulated as diabetic dietaries 1, 2, 3, 4, 5, 6 and 7 (table 2).

Diabetic dietary 1 is our basic diabetic dietary and the other six are derived from it by simple subtractions and additions. This makes the passing from one dietary to another a simple procedure.

Yields are given in household measure of basic diabetic dietary 1 in table 3, and the manner in which this food may be spread over the week in table 4

The well trained patient needs no further outline

The beginner may require a meal by meal plan, so we give a possible one for diabetic dietary 1 in table 5

It will be found that the necessary subtractions and additions to formulate the other six diabetic dietaries can be readily applied to any of these tabulations and outlines without unbalancing them. The practical advantage of this interchangeability is evident

One-half pint of cottonseed salad oil per week may be added to any diet, increasing the average weekly costs by \$0.12 and increasing the daily calories by 275. When high fat and extra calories are desired, both oil and butter may be added

The subtraction of the added half pound of butter from dietary 3, 4, 5, 6 or 7 will lower the average weekly cost to \$1.10, reduce the calories by 270 and be useful when low fat, low calory dietaries are indicated for the obese or the aged

With the outpatient group under dietetic control, indiscretions are lessened and administration costs lowered

Clinical Notes, Suggestions and New Instruments

THYROTOXICOSIS CONTINUING AFTER EXTREME OPERATIVE, IODINE AND ROENTGEN THERAPY

D. B. PHEMISTER, M.D., AND P. A. DELANEY, M.D., CHICAGO

This case of thyrotoxicosis is reported because of the extreme extent to which the thyroid gland was removed at operation and its remaining portions subsequently destroyed by pole ligations and roentgen treatment. Despite these measures and extensive iodine administration, severe thyrotoxicosis continued, and a complicating infection led to a fatal termination. At autopsy the neck was searched and no thyroid tissue was found

History—A woman, aged 41, seen by Dr. D. P. Abbott, Feb. 27, 1925, because of symptoms of nervousness, weakness, palpitation of the heart, and loss of weight, had been struck, six months previously, in the frontal region by a bolt, producing a depressed fracture of the walls of the frontal sinuses. One month later, an operation was done for the purpose of elevating the depressed bone. Soon after that she began to tire easily and to lose weight, having lost 15 pounds (6.8 Kg.) since the accident. She then developed nervousness and palpitation of the heart, which had slowly increased in severity

Examination—The patient was nervous and emotional, she was slender, weighing 106 pounds (48 Kg.). There was a fine tremor of the hands, and the pulse ranged from 90 to 100. The blood pressure was 134 systolic and 78 diastolic. There was no exophthalmos or other ocular abnormality. The thyroid gland was not palpably enlarged. There were no abnormal masses in the base of the tongue or in the neck. The heart showed no enlargement or abnormal sounds. The basal metabolism was +12. A diagnosis of thyrotoxicosis was made.

She was given compound solution of iodine 10 minims (0.6 cc.) three times a day for three weeks, and for the following four months she rested at home, being confined to bed much of the time. June 26, the symptoms were worse, with swelling of the legs. The basal metabolic rate was +37. She then took 10 minims of compound solution of iodine for one week and rested at home for one month. July 22, the condition was worse. The basal metabolic rate was +89, the weight, 95 pounds (43 Kg.). There was no exophthalmos, the thyroid was pal-

pable but not enlarged. The patient was treated by rest in bed at the Presbyterian Hospital and received 10 minims of compound solution of iodine three times a day until August 18, during which time her general condition slightly improved. The basal rate, August 5, was +61, August 20, +60, the weight, August 22, 92 pounds (41.7 Kg.). Ligation of both superior poles was done under local anesthesia. The patient was unimproved seven weeks later, and the basal rate was +53. At that time she was given compound solution of iodine, 10 minims three times a day, which was continued for seven weeks, during which time she was up and around. December 4, she was confined to bed because of edema of the legs, dyspnea, insomnia and marked nervousness. Digitalis and a mixture of amidopyrine and a barbituric derivative were given, and, December 14, the basal rate was +41. The legs remained swollen. The liver was enlarged and the left border of the heart was 1 cm. lateral to the nipple line. The pulse was from 85 to 120, blood pressure, 154 systolic and 78 diastolic, weight 105 pounds (47.6 Kg.). Jan. 13, 1926, the basal rate was +44.

Operation—January 25, the patient was given ethylene anesthesia, and the thyroid gland, consisting of two lateral lobes and an isthmus, was found to be definitely smaller than normal and moderately firm. A subtotal thyroidectomy was performed, leaving portions approximating 2 by 1 by 1 cc. at the lower poles.

Pathologic Examination—The excised specimen weighed 12 Gm. It was finely lobulated, firm and shaded from light to dark red. Microscopically there was extensive lymphatic tissue replacement, arteriosclerosis, and fibrosis of the thyroid. With Maximow's stain the thyroid alveoli were of two types. Some were of moderate size, lined by low cuboidal cells, with relatively clear cytoplasm and filled with an average amount of vesicular colloid. Others were small, resembling those of compound serous alveolar glands and containing little or no colloid. The lining cells were cuboidal to columnar and contained abundant deeply staining mitochondria. The lymphatic tissue was abundant and contained many germinal follicles. The arteries were markedly sclerotic and extensively calcified. There was both new and old fibrous tissue scattered throughout the gland.

Postoperative Course—Because of previous failures of response, no iodine was given. There was a moderate reaction, which subsided in three or four days. The patient improved slightly during the next month. Then the edema and dyspnea returned and she had extreme nervousness, diarrhea and sweats. April 20, the basal rate was +83. She was kept on compound solution of iodine, 10 minims three times a day for two weeks without benefit. An aberrant thyroid was thought of, but reexamination of the neck and base of the tongue revealed no signs of it. A roentgenogram of the chest was negative for mediastinal shadows of a thymus or intrathoracic goiter.

April 29, roentgen therapy of the thymus region was instituted. From April 29 to September 1, the patient received twenty-one roentgen treatments to the thyroid region of the neck, in a dosage of 130 peak kilovolts, 5 milliamperes, 10 inch target distance, 4 mm. aluminum filter, exposure six minutes. However, she continued to have marked symptoms of thyrotoxicosis, gradually grew worse and was confined to bed most of the autumn with cardiac decompensation.

Jan. 16, 1927, she was admitted to the hospital with swollen legs, dyspnea, and extreme nervousness. Her weight was 104 pounds (47.2 Kg.), the pulse was irregular and rapid, the basal metabolism was +28. She remained in bed and received digitalis and compound solution of iodine most of the time during the next three and a half months, with but little improvement.

April 20, the basal rate was +41. May 6, there was still marked tremor, nervousness and tachycardia but no exophthalmos.

Third Operation—An operation was done under ethylene anesthesia. As the amount of thyroid tissue left at the previous operation might have been too great, the field was again explored. However, no definite thyroid tissue could be found. The inferior thyroid arteries were identified and followed toward the trachea. Each one led to a small pea sized nodule in the region of the inferior poles, which did not look like thyroid tissue. Both inferior thyroid arteries were ligated in the hope that any thyroid tissue left in the nodules might be influenced.

Postoperative Course—There was a severe postoperative reaction for three days, after which she gradually improved, and six weeks later she was in the best condition of any time since operative treatment was started. She had gained in weight to 111 pounds (50 Kg.), she was able to walk fairly well, and the pulse ranged from 72 to 90 during a two day period of hospital observation. The basal rate had fallen to +5. After three months the thyrotoxic symptoms again grew worse, but she was able to do light work. November 5, she weighed 118 pounds (53.5 Kg.), and the basal rate was +54.

November 15, she was readmitted to the hospital with an infection of the upper respiratory tract. Cardiac decompensation with mental confusion developed. The heart improved slowly on digitalis therapy, but she remained weak and was confined to bed.

Feb 9, 1928, she was admitted to the University of Chicago Clinics, at which time she was nervous, weak and dyspneic. The heart was moderately enlarged, rapid and irregular, and there was edema of the legs. The basal rate was +77 and the blood pressure 150 systolic and 90 diastolic. Compound solution of iodine, 10 minims three times a day, was given for ten days without the slightest effect. No new physical signs had developed and various roentgen and laboratory tests were of no special interest. Between March 4 and June 1, thirteen roentgen treatments were given to the neck and upper thoracic regions with no change in her condition.

June 16, the basal rate was +74. She was then given compound solution of iodine, 10 minims three times a day, continuously for two months but remained weak, nervous and dyspneic with swollen feet. July 16, the basal rate was +65 and August 13, it was +88. Compound solution of iodine was then stopped and her condition remained much the same for two and a half months, at which time she grew worse and, November 5, was again admitted to the University of Chicago Clinics.

She had diarrhea, along with previous symptoms, and the basal rate was +85, blood pressure 180/90. Extract of suprarenal cortex was given during her five weeks' stay in bed in the hospital along with three roentgen treatments to the neck. At the end of that time her condition was but slightly improved, and the basal rate, December 9, was +68. Jan 10, 1929, the basal rate was +69 and her condition remained unchanged.

January 15, while at home, she developed a febrile condition, which was accompanied by periods of lumbar pains and hematuria. Her condition steadily grew worse with marked dyspnea and nervousness, and she died, February 27.

Autopsy—An autopsy was performed twenty-four hours later, when we learned of her death, after the body had been embalmed. The observations of importance were as follows: moderate hypertrophy of the left ventricle of the heart, vegetative mitral endocarditis and large anemic infarcts in the right kidney and the spleen, hemorrhagic glomerulonephritis. There was edema of the lower extremities and back. The structures of the neck below the hyoid bone and of the thoracic cavity were removed en masse. Of greatest interest was the fact that no tissue resembling thyroid gland could be found on careful search of the neck and mediastinum. Numerous lymph nodes were found along the course of the great vessels of the neck and the peritracheal and peribronchial regions, which were of normal appearance except for enlargement and anthracosis of the right peribronchial ones.

The remnants of the lower poles found at the last operation could not be definitely identified but small nodules of tissue from their vicinities were taken for microscopic examination. Every nodule in the neck which looked as if it might possibly be adenomatous tissue was excised and fixed for microscopic examination totaling fifteen pieces. Microscopically they all proved to be lymph nodes, of which some were normal, some hyperplastic and others fibrotic (possibly as a result of the x-rays). The tissues removed from the lower polar regions consisted of fibrous tissue, fat and nerve trunk. No definite thyroid or parathyroid tissue could be found.

The thymus weighed 6 Gm. Microscopically it contained well preserved Hassall's corpuscles and a small amount of lymphatic tissue. The suprarenals were slightly smaller than normal and showed normal relations of cortex and medulla.

Microscopically there were no changes. The ovaries, tubes and uterus were normal in appearance, and microscopic examination of the ovaries showed no changes. The brain and spinal cord were not examined.

Removal of the tongue and nasopharynx was not permitted.

COMMENT

The fact that at autopsy no thyroid tissue was found in the neck does not exclude its existence, since serial sections were not made of the entire structures and very small amounts would easily escape detection. Since the tongue and nasopharynx were not examined, the question arises as to the presence of aberrant thyrotoxic gland tissue in those locations as being responsible for the continued symptoms. For the following reasons this appears to be extremely improbable. Aberrant thyroid tissue was suspected during life, and the base of the tongue, nasopharynx and upper part of the neck were repeatedly examined for it with negative results. A search of the literature revealed only two very questionable cases of thyrotoxicosis due to disease in an aberrant thyroid, reported by Galisch¹ in 1894 and Strauss² in 1906. The finding of a normally shaped and situated thyroid gland is against the presence of an associated aberrant thyroid at the base of the tongue, since the thyroid develops entirely from the median anlage at the base of the tongue and, according to Schilder³ and Erdheim,⁴ absence, malformation or a pyramidal lobe of the cervical structure is the common finding when lingual thyroid is present. The tendency in aberrant thyroid is for the development of hypothyroidism instead of hyperthyroidism. It was reported in eighteen cases of lingual goiter collected by M. L. Montgomery of this clinic. He also found six cases of thyroid insufficiency which first appeared after removal of a lingual thyroid.

The facts that the gland removed at the second operation showed histologic features compatible with thyrotoxicosis and that, after the ligation at the third operation of the inferior thyroid arteries to the very small masses in the inferior polar regions, the basal metabolic rate fell to +5 and the patient had a temporary period of definite improvement speak for the thyroid in the neck as the seat of the disease.

Pemberton⁵ has pointed out that there is no very exact relationship existing between the amount of gland removed and the completeness of disappearance of symptoms and has emphasized the point that as complete a disappearance of symptoms and return of remaining portions to a normal microscopic appearance will usually be obtained by removal of from 65 to 85 per cent of the structure as by removal of much larger proportions, as advocated by Richter. It should be remembered that in the earlier days of operative treatment prompt recovery often followed removal of only one half of the gland. However, experience has shown that continuation or return of symptoms is often due to too much gland left behind and removal of an adequate amount of the remaining portion results in a cure as shown by the reports of Richter,⁶ Clute,⁷ and Collier and Potter.⁸ But this is not always the case, as rarely have patients remained thyrotoxic after nearly all the remaining portion has been removed.

We have been unable to find reports in the literature of cases similar to this one, but we know from personal communication that Pemberton has had a similar experience.

The question arises as to whether or not in such cases the thyroid gland is the seat of the disease, as is now generally assumed for thyrotoxicosis. That it is the seat is readily explainable on the assumption that a very small amount of overlooked diseased thyroid may have the necessary effect when other structures, such as the sympathetic nervous system, which

are secondarily influenced, are unusually susceptible to the action of its secretion, i. e., hypersensitization of body tissues to a normal or altered thyroid hormone

SUMMARY

A case of thyrotoxicosis was uninfluenced by prolonged and repeated administrations of compound solution of iodine, ligation of both superior poles, extensive subtotal thyroidectomy and extensive roentgen treatment. Improvement then followed bilateral ligation of the inferior thyroid arteries supplying pea sized masses at the lower poles, but the disease soon recurred in severe form and compound solution of iodine and roentgen therapy were again used without benefit. Vegetative endocarditis finally supervened, with a fatal termination.

An autopsy was performed and no thyroid tissue was found. The tongue and nasopharynx were not examined at autopsy, but it is extremely improbable that there was any thyroid tissue in those regions.

SAWDUST DERMATITIS

OSCAR L. LEVIN, M.D., NEW YORK

Attending Dermatologist, Beth Israel and Sea View Hospitals. Associate Dermatologist, Mount Sinai and Montefiore Hospitals. Consulting Dermatologist, Rockaway Beach Hospital.

During the past three decades, the specialty of dermatology has grown increasingly comprehensive. In fact, the subject of dermatitis has grown to considerable economic importance since the introduction of compensation laws. In a dermatologic case recently referred to me, I found that a dermatitis of the hands and forearms resulted from the handling of sawdust. The occurrence of dermatitis venenata from contact with plants and wood has been known for many years. It is less well known, however, that so apparently innocuous a substance as sawdust contains chemicals that may arouse a disabling occupational disease. The literature contains rather meager references to this subject. It is my purpose in this paper to record an illustrative case.

REPORT OF CASE

History—A S., a married woman, aged 50, a sweeper in a department store, referred to me, Aug. 13, 1931, complained of an intensely itchy eruption of both hands of seven weeks' duration. It had first appeared as small "itchy blisters" on all the fingers and both hands. New blisters continued to appear as old ones dried. Shortly after the onset, the skin became dry and cracked. The patient experienced difficulty in bending her fingers, and attempts to close her hands caused pain. She continued working until three weeks prior to her first appearance in my office.

She said that the condition was produced by the sawdust that she handled in her work. Her work consisted of sweeping in a department store after it had been closed for the day. She moistened the sawdust with water and threw handfuls of it on the floor. This was then swept away with a broom. She had been engaged in this occupation for seven weeks. No history of a previous skin condition could be elicited.

Treatment had consisted of applications of bland oils, but there had been no relief and she was finally compelled to stop work.

Dermatologic Examination—Examination of the skin revealed an eruption of the fingers and hands. All the fingers and both hands were swollen and appeared enlarged. The right hand was more affected than the left. The skin of the affected areas was red, swollen, edematous, vesicular and torn. Small and large vesicles were present. Many were exuding a thin serum. The palms showed large denuded areas that were bright red, moist and surrounded by undermined, frayed, epidermal borders. Scattered over the skin were discrete and aggregated vesicles, some of which had dried and were covered with crusts. The front of both forearms showed dark red, papular, thickened patches with some scaling. Over the front of the left elbow was an ill defined, large, superficial, moist, excoriated patch.

Careful inquiry was made as to the possible etiologic factors. The diagnosis of dermatitis venenata was made on clinical

grounds and that of sawdust dermatitis was confirmed by positive patch tests. In the performance of the patch test, sawdust moistened with water was applied to the skin of the back. Twenty-four hours later the tested area was bright red, elevated and covered with numerous vesicles. The dermatitis which developed extended rapidly to cover an area that was about three times as large as the originally tested area, and the inflammation persisted for about a fortnight.

The skin was treated and cured with wet dressings, pastes and roentgen therapy. Nine days after returning to her work a fresh, similar eruption appeared on the fingers and hands. The patient stated that immediately after handling the moistened sawdust again she began to suffer from itching, which was soon followed by an eruption. The recurrence was characterized by an acute efflorescence of bright red, vesicular, edematous, oozing, patchy lesions.

The patch test has proved to be of particular value in the detection of an obscure etiologic excitant in cases of eczema (dermatitis). This depends on the fact that the surface epithelium will often react on contact with chemicals when the deeper tissues may not.

The technic is extremely simple. It consists of the application of the suspected substances to the uninjured surfaces of the skin. This is done by soaking small pieces of gauze in the material and applying them to the normal skin, preferably on the back. This saturated patch is covered with a larger dry patch and secured by means of adhesive tape. Several tests may be made at one application and definitely marked for future observation. These patches are permitted to remain for twenty-four hours, at which time they should be removed and the reactions noted.

There is no universal method that is efficacious in the testing of all hypersensitive skin conditions. The type of eruption with which I am concerned in this paper is dermatitis venenata and that of sawdust dermatitis, as confirmed by positive contact or patch tests. In this condition the patch test has its principal use, for it alone can aid in the quest of the etiologic factor and in the study of the dermatitis. And, once again, the patch test has proved efficacious in definitely establishing a diagnosis of dermatitis venenata and its relation to occupational diseases as ruled under the workmen's compensation law.

Dermatitis venenata is described under the aforementioned law as "any process involving the use of or direct contact with acid, alkalis, acids or oils capable of causing dermatitis (venenata)".¹ Since in this case a definite diagnosis has established the existence of a dermatitis venenata and also that of a sawdust dermatitis, the sawdust being a screened product of sawmills in which various varieties of woods are employed, it is obvious that the isolated alkaloid from sawdust is the offending factor. Therefore, sawdust dermatitis constitutes an occupational disease which should be compensated by law.

COMMENT

Investigation has not disclosed the record of any chemicals being used in the manufacture of sawdust. Sawdust is simply the screened product of the sawmills. The chips and sawdust are put between two grinding stones and pulverized. This is screened and packed in sacks. Steam or water is introduced in limited quantities to prevent excessive heating from friction.

Literature on sawdust dermatitis has disclosed that satinwood affects the skin without affecting the conjunctiva, mouth or penis. The rash disappears in a few days and is said to be caused by the oil in the wood. However, Auld² examined and extracted 1 per cent of oil from the sawdust and found that this oil did not give rise to irritation. He isolated an alkaloid, which he called chloro-ylonnine, and thus, it is believed, is the cause of the dermatitis. This alkaloid and its salts, the hydrochlorides, are activating agents to two out of every three persons. This chemical is a powerful irritant, and, according to Cash,³ the poison requires twenty-four days of latency to develop its effects.

METHOD FOR THREADING NEEDLES—POTH

VOLUME 100
NUMBER 8

Spillman⁴ has recorded a series of eruptions from handling freshly cut oak but is uncertain whether the juice of the oak was the responsible agent or some vegetable growth on the bark.

The symptoms of satinwood dermatitis are intense irritation, followed by heat, redness, swelling and pain. At a later stage, the skin becomes moist and peels off. Ebony and teak also produce inflammatory skin disorders, accompanied by constitutional symptoms.

Japanese hardwood, or "togayasa," causes a dermatitis and a dark brown pigmentation, accompanied by a toxic action on the digestive and renal organs. Rosewood, mahogany and birch wood are frequently offending agents in cases of skin irritation among wood workers. Erythema multiforme and pustular acne in workers handling woods found in the central states are probably caused by mechanical action only, the irritating and abrasive action of the woods giving rise to minor injuries which present numerous portals of infection.

The erythema and thickening of the skin of the hands in laborers who saw chestnut wood has been described by Horland⁵ as the "crocodile hand."

SUMMARY

This rare but prevalent case of sawdust dermatitis was diagnosed by the clinical picture presented and confirmed by means of the positive patch test. The patient made an uneventful recovery.

Since it is known that sawdust contains an alkaloid, which chemical is a powerful irritant, sawdust dermatitis should be classified among the occupational diseases ruled under enactments of the workmen's compensation law.

A SIMPLE METHOD FOR THE RAPID THREADING OF NEEDLES

EDGAR J. POTTS, PH.D., M.D. SAN FRANCISCO

The use of fine milliner's needles and silk, as advocated by Kocher, Halsted and Cushing, entails the threading of numerous needles. This task is tedious, time consuming and often difficult, especially when medium, heavy and braided silks are used. The method described here is presented because of its simplicity.

A piece of wire is selected according to the size of needle and thread to be used. The accompanying table gives the best corresponding sizes of wire, needles, and suturing materials.

FIG. 1.—A clamp and wire from which threader is made. B tip of clamp with wire loop. C fine silk thread through loop pulled tight to shape the wire. D finished apparatus.

The ends of a piece of wire approximately 3 cm long are grasped in a needle holder to form a loop. A fine silk suture is passed through the loop and pulled tight to shape the end of the wire so that it will readily pass through the eye of a needle. As many as twelve needles can be threaded onto this doubled wire. The suture material is passed through the loop. The needles are then grasped between the forefinger and the thumb so that they will pass freely along the wire. With a

quick movement, the suture material is pulled through all the eyes. If this maneuver is done slowly, or if any of the needles have defective eyes, the silk will be frayed and will not pass. Continuing to hold the needles between the index finger and the thumb, one can pull through and cut off with its needle the required silk for each suture. A convenient instrument for

Fig. 2.—A needle threader with needles being threaded over the loop. B tip of A enlarged. C, needles threaded over loop. D suture material passed through the loop. E needles pulled over the suture. F needles threaded by this method: 1 Kirby silk and number 16 needle, 2 size A silk twist and number 9 needle, 3 size B silk twist and number 9 needle, 4 size C silk twist and number 9 needle, 5 braided silk number 6 and number 9 needle.

cutting the sutures is made by mounting a double edged razor blade on a cork. In this manner one can easily thread a gross of ordinary number 9 milliner's needles with fine silk in an hour. Likewise, braided silk is threaded into needles with small eyes.

Best Corresponding Sizes of Wire, Needles, and Suturing Materials

* This size wire is ordinarily used for stylets in hypodermic needles.

Also this procedure can be applied at the operating table. If a wire loop with a needle threaded onto it is available on the instrument table, it can be used for the ready rethreading of a continuous suture which has become unthreaded during the course of an operation. This might save one much time and embarrassment especially when fine needles are used, as in suturing blood vessels.

APPENDECTOMY FOR SWALLOWED CLINICAL
THERMOMETER

GEORGE K. NUTTING, M.D., WASHINGTON, D. C.

Large foreign bodies are rarely swallowed except by children and insane persons. Most of these foreign bodies pass through the gastro-intestinal tract and are expelled in the feces. Operation for their removal from the intestine is rarely necessary.

Fig 1—Clinical thermometer in right lower quadrant of the abdomen

The passage of foreign bodies through the intestinal canal is often surprising. Lediard¹ reports the passage of a 3¼ inch latchkey. I have observed two cases in which large open safety pins passed through without difficulty. Lodgment is an accident and will probably occur at the pylorus, at the ileocecal valve or at one of the flexures of the colon. A lodged foreign body may cause ulceration, perforation, abscess, peritonitis or intestinal obstruction. Operation is necessary in these cases.

I report a case in which a swallowed clinical thermometer was removed from the colon by appendectomy. This is a rare surgical procedure for the removal of intestinal foreign bodies. Review of the literature shows only the case of Stangl,² in which a nail was removed from the cecum.

REPORT OF CASE

J. K., a white man, aged 28, was brought to Gallinger Hospital, Aug 28, 1932, by the police for observation and report of his mental status. He had attempted suicide by jumping in front of a street car. He was put to bed and a physical examination showed general abrasions and contusions. An orderly was instructed to take the patient's temperature by rectum. He inserted the thermometer and left the room for a short interval to attend another patient. When he returned, the thermometer was missing. Rectal examination and a thorough search of the bed and room failed to reveal the thermometer. The patient finally admitted having swallowed it. A roentgenogram of the abdomen showed a clinical thermometer in the stomach. Daily pictures were made to trace its movement. By the fifth day it had progressed to the right lower quadrant (fig 1). Repeated examinations showed that it remained stationary in that location. At no time did the patient have symptoms referable to the foreign body. I saw the patient in consultation, September 29, and advised operation because of the apparent lodgment.

Tribrom-ethanol and gas anesthesia was used. The abdomen was explored through a right rectus incision. The thermometer

The passage of foreign bodies through the intestinal canal is often surprising. Lediard¹ reports the passage of a 3¼ inch latchkey. I have observed two cases in which large open safety pins passed through without difficulty. Lodgment is an accident and will probably occur at the pylorus, at the ileocecal valve or at one of the flexures of the colon. A lodged foreign body may cause ulceration, perforation, abscess, peritonitis or intestinal obstruction. Operation is necessary in these cases.

I report a case in

Fig 2—Appendix containing thermometer

was palpated within the ascending colon. It was milked along the intestine and out into the appendix after the meso-appendix had been ligated and divided. Appendectomy was then performed with the thermometer in the appendix (fig 2). An uneventful recovery followed the operation.

1606 Twentieth Street N.W.

DYSTOCIA FROM RETRODISPLACEMENT OF LEFT FORE
ARM COMPLICATED BY PRENATAL SUBGLENOID
DISLOCATION OF THE LEFT SHOULDER

P. L. THIBAUT, M.D., NEW ORLEANS

This case is reported because of its rarity. DeLee¹ states that approximately twenty-five cases have been reported, the majority by European obstetricians. All the cases, beginning with that of Sir J. Y. Simpson² in 1850, occurred in women who had already borne children, multiparas being more prone to irregular action of the uterus than primiparas. This anomaly of attitude involved one arm in all but two cases, in these, both arms were retrodisplaced. Delivery was spontaneous in two of the cases. A few forceps extractions were performed, with or without injury to the fetus. Version proved the method of choice in the majority of the cases. In one case, forcible extraction with Tarnier forceps caused decapitation of the child. In all cases diagnosed before delivery, an attempt at reduction of the position was made, and, in most instances, was successful.

REPORT OF CASE

Mrs. E. H., aged 23, came to my office during her third month of pregnancy. She was in good physical condition except for her weight, which was 170 pounds (77 Kg.). Her pelvic measurements were normal. There was nothing in the family or personal histories having any bearing on the case. She had borne two children. The first, a girl weighing 8 pounds 4 ounces (3,742 Gm.), was delivered with forceps after thirty-six hours of labor, Jan 17, 1930. The difficulty in this case, as far as I could learn, was due to an impacted head.

March 16, 1931, a second girl, weighing 8 pounds 13 ounces (3,997 Gm.), was delivered normally after four and one-half hours.

Aug 10, 1932, the patient was admitted to Hotel Dieu at 3 a.m., uterine contractions having begun two hours earlier.

At 3:30 I examined her vaginally. The uterus showed a two fingers' dilatation. The position was right occipito-anterior.

At 5:40 the dilatation had increased to four fingers. The pains were slightly irregular and showed no increase in intensity. The patient at no time gave any evidence of much suffering.

At 8:30, being convinced that some impediment, not apparent, accounted for the delay, I sent the patient to the delivery room. Ethylene and ether anesthesia was given. I found the dilatation complete, the bag of waters protruding well into the vagina. I ruptured the bag, and a large quantity of amniotic fluid escaped. The head, however, failed to engage. I then introduced my hand into the uterus and found the left forearm wrapped around the back of the child's neck. Attempts to dislodge the forearm from this position were unsuccessful, so version was decided on. On account of the large size of the fetus (9 pounds 13 ounces, 4,450 Gm.), I was unable to bring down both feet before turning, so had considerable difficulty in delivering.

At 8:59 the extraction of the child, a boy, was accomplished. As the baby was breathing poorly, he was placed in the Drinker respirator while I gave my attention to the mother. The baby remained in the respirator until the arrival of Dr. R. E. de la Houssaye, who was to have charge of him. As he was examining the baby and making traction on the left arm, the click of the head of the humerus snapping back in place was distinctly audible to those of us who were in the room.

I judge that the dislocation was caused, in utero, by forcible elevation of the elbow impinging on the horizontal ramus of the pubis. This elevation occurred with each contraction of the uterus in nature's attempt to force the head to engage. Repeated contractions finally lifted the head of the humerus from its position in the glenoid cavity, causing a subglenoid dislocation.

² Simpson, J. Y. Obstetric Memoirs, 1850.

tion. The dislocation, which was not diagnosed before delivery, accounted for my futile attempts at reduction of the anomaly. The mother and baby showed no ill after-effects.

COMMENT AND CONCLUSIONS

This case presents four points of special interest

(a) The anomaly of attitude was unusual
(b) It was necessary to invade the uterine cavity for a proper appreciation of the conditions presenting. Neglect of this complete examination might have led us into the error of using solution of pituitary or of resorting to forceps to finish the delivery. Either of these procedures might prove disastrous, to the mother by a possible rupture of the uterus, to the child by mutilation.

(c) Version and extraction constitute the method of choice.

(d) As far as I have been able to ascertain, this is the first case of retrodisplacement of the forearm complicated by dislocation of the shoulder.

5216 Pitt Street.

A QUICK METHOD OF FIXATION, DEHYDRATION AND EMBEDDING OF TISSUES

E. B. ERSKINE, M.D., NEW YORK
Lieutenant, M.C., U.S. Navy

The need for quick methods of fixation, dehydration and staining of tissues is evinced by an increasing number of suggestions in the form of articles published. To this number I believe it is my duty to add my contribution, for, since the time factor is conceded to be most important when consistent with practical results, the method in use in the laboratory of the U.S. Naval Hospital requires forty-five minutes for fixation, dehydration, embedding and cutting of fresh tissue. Staining is done by the usual methods or, when greater haste indicates or other considerations suggest it, the Rhamy triple stain method is used.

The method is largely the product of the efforts of A. L. Maimes, pharmacist's mate first class, working at the U.S. Naval Medical School and in this laboratory.

Tissue sections prepared and stained in the following manner during the past three years have been filed with sections which have been prepared in the slower routine manner and have been found to remain in a similar state of preservation. Fresh tissue is cut into convenient size and about 2 mm thick. This tissue is placed in a test tube of neutral "solution of formaldehyde-U.S.P." diluted 1:10 and gently boiled for a period of three minutes, during which time five test tubes, appropriately labeled and containing respectively (1) 80 per cent alcohol, (2) 95 per cent alcohol, (3) 100 per cent alcohol, (4) chloroform and (5) 95 per cent alcohol, are placed in a water bath and the temperature brought to 55°C.

The temperature is accurately gaged by a thermometer placed in the test tube prior to placing the tissue in the tube, whereupon the thermometer is dried and placed in the succeeding tube solution. It will be noted later that tube 5, containing 95 per cent alcohol, serves no purpose other than a check on the temperature during the time the tissue is in tube 4.

The fixation of the tissue in boiling formaldehyde solution having been completed, the solution is poured off and the tissue dried on blotting paper. It is then placed successively in the solution contained in tubes 1, 2, 3 and 4 for a period of five minutes in each.

The next two steps are carried out in the embedding oven at the same temperature (55°C). Chloroform and paraffin (equal parts) and paraffin are always kept in our oven at the temperature mentioned and consequently are always available for this method. The tissue is kept in each solution for five minutes whereupon it is embedded in paraffin, immediately chilled in a pan of ice water, cut and mounted on a slide.

It will be readily appreciated that tissue which has been previously fixed in formaldehyde and small delicate tissue masses such as mice ovaries to be diagnosed in the Aschheim-Zondek test, need not be boiled in the formaldehyde solution. It is our habit in the latter instance to allow the mice ovaries to stand in 10 per cent solution of formaldehyde at room temperature for the length of time necessary to stabilize the temperature of the dehydrating solutions in the water bath.

U.S. Naval Hospital

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY OF THE AMERICAN MEDICAL ASSOCIATION HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
H. A. CARTER, Secretary

COLD-QUARTZ ULTRAVIOLET GENERATOR ACCEPTABLE

The Cold-Quartz Ultraviolet Generator (a trade name) is manufactured by the Electro Therapy Products Corporation, Ltd., of Los Angeles. The apparatus consists essentially of a Geissler tube (grid) made of fused quartz, a step-up transformer and a regulating choke coil. The quartz tubing is about 9 mm in diameter and about 7 feet in length, forming a five turn hexagonal grid. It is highly evacuated of air and the space is supplanted with an atmosphere of rare gases, neon, krypton and argon, and a few drops of mercury.

The Cold-Quartz Ultraviolet Generator operates on 110-120 volt alternating current. The body model draws on the secondary side of the transformer 50 milliamperes and the orificial model, 15 milliamperes. The units will not operate on direct current without additional special apparatus.

The Cold-Quartz Generators are made in several models. The Cold-Quartz Ultraviolet Generator, Model C-7, is a combination of complete body and orificial generator with demountable grid and special type orificial units. The shipping weight is 68 pounds.

The Cold-Quartz Ultraviolet Generator, Model B-7, is a body irradiation type. The shipping weight is 62 pounds.

The Cold-Quartz Ultraviolet Generator, Model S-7, is arranged for the selection of four cavity orificial units. The shipping weight is 43 pounds.

The Cold-Quartz Ultraviolet Generator, Model C-7-10, is a more elaborate reproduction of Model C-7. The shipping weight is 145 pounds.

The Cold-Quartz Ultraviolet Generator, Model P-7, is a portable orificial generator. The shipping weight is 23 pounds.

Figure 1 shows the combination body and orificial model.

The Council examined an orificial model of the Cold-Quartz Generator. This quartz tubing is about 7 mm in diameter, about 6½ inches in length, and is slightly curved and tapered at its distal end. However, the emission characteristics are alike. The orificial model examined is designed to operate on 110 volts, 60 cycle alternating current. By means of a step-up transformer, 500 volts is impressed on the terminals of the tube. The current flowing in the tube was between 25 and 15 milliamperes. The maximum power consumed by the apparatus, transformer, grid and connections, was from 60 to 65 watts.

When the luminous tube of the Cold-Quartz Ultraviolet Generator was placed lengthwise against the slit of the quartz spectroscope and a thermopile radiometer was used, it was found that 96.1 per cent of the total erythematogenic rays (of wavelengths 3130 angstrom units and shorter rays) are emitted by the 2537 angstrom line. By means of a filter method it was found that 97.8 per cent of the erythematogenic rays are contained in the strong emission line at 2,537 angstroms. This line is highly germicidal and will penetrate the skin. The intrinsic intensity of the 2,537 angstrom line is relatively high, being 215 microwatts per square centimeter at the surface of the quartz tube. The ultraviolet energy emitted on high voltage is 1.6 times that emitted at low voltage.

With the use of an E 31 Hilger quartz spectroscope spectrographs of the light emitted by the Cold-Quartz Orificial Model

Fig. 1—Cold Quartz Ultraviolet Generator

were photographed by Prof I S Bowen of the Department of Physics in the California Institute of Technology With a portion of the tube of the Cold-Quartz Lamp placed directly in contact with the slit of the spectroscope, exposures both of thirty seconds and of two minutes were made on Schumann plates, which are highly sensitive to radiations in the short wavelength region

The short wavelength lines in the ultraviolet region known as 1,849, 1,942, 1,973, 2,028 and 2,053 of the mercury spectrum were revealed on Schumann plates, as well as other lines of the mercury spectrum to and including line 4,358 Figure 2 is a reproduction of the spectrum emitted by the Cold-Quartz Ultraviolet Generator

The evidence submitted by the firm indicates that the quantity of proportion of ultraviolet rays at lines 1,840, 1,942 and 1,973 emitted by the lamp examined by Professor Bowen is small In the spectrogram accompanying Professor Bowen's report these lines are quite weak

Dr S S Mackeown conducted an investigation and submitted evidence proving that the temperature of the lighted tube of the Cold-Quartz Ultraviolet Generator, when inserted in the vagina of a 30 pound dog, did not exceed 44.5 C (112.1 F) with a current of 15 milliamperes flowing through the lamp When the tube is inserted in a cavity in the body it is cooled by direct contact with the tissue, and the small amount of heat that is generated by the tube is carried away by the blood stream

The summary of a report¹ of an investigation carried out at the University of Illinois by Drs Albert Bachem and C I Reed reads

1 The radiation of the cold quartz body lamp is extremely constant after a building up time of about one minute, a factor of great importance concerning accurate dosage.

2 Most of the ultraviolet light of the cold quartz lamp is concentrated into the spectral area around 254 mμ (2,537 Å)

3 The ultraviolet given off by the cold quartz lamp has enough penetrating power through the atmospheric air (and through the epidermis) to cause biological and therapeutic effects

4 The light of the cold quartz lamp has definite antirachitic power, this makes the lamp useful for the prevention and healing of rickets

5 The antirachitic effect of cold quartz light is attributable more to the abundance of rays of short wavelength in the region of 254 mμ (2,537 Å) than to the weak components of longer wavelength

In another report,¹ prepared by Dr Harry Goldblatt at the request of the Council and under a grant by the Council, the author writes in the conclusions

It has been shown that the radiations from the Cold Quartz mercury lamp are powerfully antirachitic Direct irradiation for three seconds daily prevented the development of rickets in rats fed on a rickets producing diet Direct irradiation for ten seconds daily brought about complete healing of rickets in severely rachitic rats Under the conditions mentioned in the text, exposure of ergosterol dissolved in olive oil to the radiations from a cold quartz mercury lamp for only one minute resulted in the antirachitic activation of the solution of which 0.002 mg of irradiated ergosterol and 0.001 cc of irradiated olive oil together prevented and cured rickets in rats The minimal protective and curative doses were not determined

Fig 2—Spectrum

ergosterol and 0.001 cc of irradiated olive oil together prevented and cured rickets in rats The minimal protective and curative doses were not determined

The Council on Physical Therapy has not received from the firm conclusive evidence to substantiate the claim that radiations from this lamp will cure or protect against rickets in children It is reasonable to assume, however, that the cure of rickets in animals with radiations from the Cold-Quartz Ultraviolet Generator might well be interpreted as sufficient evidence, and equal

¹ Mimeograph copies can be secured from the Council on Physical Therapy on receipt of a self addressed stamped envelop

effectiveness may be presumed when the radiations are applied to rachitic babies

A point still under consideration is whether the radiation from the strong emission line 2,537 will at the same time destroy vitamin D as well as activate it The cold-quartz generator seems to have a place in the treatment of skin diseases and infections, but this has not been fully established

The Council does not recommend the Cold-Quartz Ultraviolet Generator for use in dental therapeutics Conclusive scientific evidence must be presented to substantiate its efficacy as a dental therapeutic agent before the Council will accept such claims The use of the Cold-Quartz Ultraviolet Generator by a layman as a sunlamp is considered dangerous The Council advises the use of goggles by the operator and the patient

On the basis of the foregoing evidence that the lamps will activate ergosterol and create vitamin D, the Council on Physical Therapy declares the aforementioned Cold-Quartz Ultraviolet Generators eligible for inclusion in its list of acceptable devices for one year

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION

P N LEECH, Secretary

DEXTROSE (See New and Nonofficial Remedies, 1932, p 262)

The following dosage forms have been accepted

Sterile 5% Dextrose Solution in Vacoliter Container Each 100 cc contains dextrose, U S P, 5.25 Gm

Prepared by Don Baxter Intravenous Products Corporation, Chicago

Sterile 10% Dextrose Solution in Vacoliter Container Each 100 cc contains dextrose, U S P, 10.5 Gm

Prepared by Don Baxter Intravenous Products Corporation, Chicago

SCOPOLAMINE STABLE-ROCHE (See New and Nonofficial Remedies, 1932, p 354)

The following dosage form has been accepted

Ampules Scopolamine Stable Roche $\frac{1}{100}$ gr 1 cc Each ampule contains 1.2 cc. (1 cc contains 0.0006 Gm of scopolamine hydrobromide)

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT

P N LEECH, Secretary

SOME ENDOCRINE PREPARATIONS OF THE ROVIN LABORATORIES NOT ACCEPTABLE FOR N N R

The A M Rovin Laboratories, Inc., Detroit, submitted for consideration of the Council a series of "uniglandular" products The firm submitted no advertising for the products but presented descriptions and statements of the claims made for the various preparations, together with trade packages of each The Council found the following unacceptable for the reasons stated

Corpus Luteum Solution (Rovin), it is stated, "represents" 19½ grains of fresh, separated corpus luteum in 1 cc It is not claimed to be assayed biologically As a "composite mixture of the various hormones present in the Corpus Luteum" it is proposed for use in dysmenorrhea, the nausea of early pregnancy, habitual abortion without demonstrable cause, and sterility The Council held on the basis of available evidence that the use of ovarian preparations containing or claimed to contain any but the follicular hormone (for which an acceptable method of assay is available) is not justified except for purposes of controlled experimentation (THE JOURNAL, Jan 20, 1932, p 402) Since no supporting evidence is offered in favor of this preparation, it is not acceptable for New and Nonofficial Remedies

Lymphatic Solution Rovin, it is stated, "represents" 35 grains of fresh lymphatic glands in 1 cc The firm states further that the chemistry and therapeutic indications of this gland are still in the experimental stage No evidence for the pre

sumptive value of this indefinite preparation having been submitted, it is unacceptable for New and Nonofficial Remedies

Kidney Solution (Rovin), it is stated, "represents" 30 grains of fresh kidney substance in 1 cc. The firm further states that "the chemistry and therapeutic indications of this gland are still in the experimental stage. It is claimed to reduce albumin and increase urea." No evidence for the therapeutic value of this indefinite preparation having been presented, it is unacceptable for New and Nonofficial Remedies

Mammary Solution (Rovin), it is stated, "represents" 40 grains of fresh mammary substance in 1 cc. The firm further states that "Mammary gland preparations are believed to induce contraction of the uterus and are employed in uterine hemorrhage and discharge. They have also been suggested in deficient lactation, atrophy of the breasts, and in ovarian and tubal diseases." On account of the slight evidence for the value of mammary gland preparations in the course of many years, the Council refused further recognition of them as long ago as 1921. No new or convincing evidence is offered for the preparation of the A. M. Rovin Laboratories, Inc., and the product is therefore unacceptable for New and Nonofficial Remedies

Ovarian Solution (Rovin), it is stated, "represents" 46 grains of fresh cow ovarian glands. As a "composite solution of the active hormones in the fresh ovarian tissue" it is claimed to be "indicated wherever there is a deficiency or irregularity of ovarian action." The product is not stated to be biologically assayed by an acceptable method, or by any method. This preparation is therefore not acceptable for New and Nonofficial Remedies for the same reason that excludes Corpus Luteum Solution (Rovin)

Ovarian Residue Solution (Rovin), it is stated, "represents" 31 grains of fresh ovarian residue from cows' ovaries in 1 cc. and "is indicated in late development of puberty, infantilism, irregular menstruation at puberty, etc." It is not stated to be biologically assayed by an acceptable method, or by any method. It is therefore unacceptable for New and Nonofficial Remedies for the same reason that excludes Corpus Luteum Solution (Rovin)

Placenta Solution (Rovin), it is stated, "represents" 6 to 7 grains of fresh placenta substance in each cubic centimeter and is not biologically assayed. It is claimed that the preparation is "indicated where it is desired to inhibit the secretion of milk while preparing the breasts for such activity" and "in mothers whose breast fed infants do not thrive." These claims appear to be purely theoretical, no evidence being offered in support. The preparation is therefore not acceptable for New and Nonofficial Remedies

Thyroid Solution (Rovin) is claimed to represent in 1 cc. 0.05 per cent of iodine. The firm states that it is not biologically tested and does not give the method used to determine the iodine content. Since there is no evidence that solutions of thyroid have any advantage over the dry gland, this indefinite product is illogical and superfluous and therefore unacceptable for New and Nonofficial Remedies

Pituitary Anterior Lobe Solution (Rovin) is stated to "represent" in 1 cc. 18½ grains of fresh anterior pituitary lobe and is not claimed to be biologically assayed, but is claimed to "represent a composite mixture of the various hormones in the Anterior Lobe." Since it is not assayed, and since no details as to the method of manufacture or evidence as to its therapeutic value are presented, this preparation is unacceptable for New and Nonofficial Remedies

Pituitary Anterior Lobe Sex Hormone Solution (Rovin) is stated to consist of a solution of the sex hormone of the anterior pituitary lobe which has the property of maturing the immature rat. It is stated to be biologically assayed and the method of assay is outlined. Since there is submitted however no evidence whatever as to its value as a therapeutic agent, this preparation is unacceptable for New and Nonofficial Remedies

Suprarenal Gland Solution (Rovin) it is stated "represents" 30 grains of whole fresh suprarenal gland in 1 cc. No method of assay or of manufacture is given. The firm states that it probably consists of a composite mixture of the various hormones of the whole suprarenal gland and "as such it is indicated in Asthma, Bronchial Spasms, Addison's Disease, Cholera and Graves Disease. The extreme indiffiniteness of the composition of this product and the lack of evidence of

its therapeutic value render it unacceptable for New and Nonofficial Remedies

Suprarenal Cortex Solution (Rovin), it is stated, "represents" 77½ grains of fresh suprarenal cortex in 1 cc. No method of assay or of manufacture is given. It is claimed to be "indicated in hypo-adrenia, true Addison's disease and the minor functional types." In the absence of information as to the method of standardizing or of control of the composition of this product as well as lack of evidence as to its therapeutic value, it is unacceptable for New and Nonofficial Remedies

Thymus Solution (Rovin), the firm claims, "represents" in 1 cc. 84 grains of fresh thymus gland. The firm states that the product is not biologically assayed and furnishes no statement of the method of manufacture or control. The claim is advanced that "Thymus Solution, when combined with hypophyseal extract, acts specifically to relieve exhaustion in all cases of childbirth in which it is applied." There is no evidence of the therapeutic value of this product and it is therefore unacceptable for New and Nonofficial Remedies

Liver Solution (Rovin) is stated to be biologically tested by its ability to lower blood pressure, but no protocols of tests or of method of manufacture are supplied. It is claimed to be "indicated in Hypertension, Eclampsia and many conditions of defective hepatic intoxication." The value of liver solution in the reduction of hypertension has not been proved, and no supporting evidence is offered by the firm. The product is unacceptable for New and Nonofficial Remedies

Spleen Solution (Rovin) "represents," it is stated, 80 mg of solids coming from the spleen, for Spleen Solution 500% (Rovin) no statement of composition is given. The firm states that "these solutions are standardized on the basis of glandular solids in the finished solution" but gives no details of the process of manufacture. Spleen Solution (Rovin) is claimed to be indicated in eczema and urticaria. No acceptable evidence exists as to the value of spleen in these conditions and the firm has submitted none. These spleen products are therefore unacceptable for New and Nonofficial Remedies

Orchic Extract (Rovin) is stated to be suitable for injection and to consist of "a stable potent solution, each cc representing the essential male sex principle in 227 grams of fresh Orchic substance." The product is stated to be standardized by its growth stimulating effect upon the combs of capons. The firm states that "it is reasonably safe to assume that the male hormone can stimulate the secondary sex characteristics in the human." Orchic Solution (Rovin), it is claimed, "represents" in 1 cc. 55 Gm. of fresh orchic glands from beef and "consists of the hormones from fresh Orchic glands, whose function is to control the masculine sex characteristics." The firm states that this product does not lend itself to standardization, and no method of manufacture or of control is given. Prostate Gland Solution (Rovin) is claimed to be therapeutically useful "in atrophy and diseases of the testicles, also in enlarged prostate gland." It is claimed to "represent" in 1 cc. 35 grains of fresh prostate gland. No method of manufacture or of control is given. The mode of administration is not indicated. The Council knows of no scientific evidence that orchic substance or prostate gland substance taken by mouth has any effect on the human being. Furthermore the work of Gallagher and Moore showed that after injection no action can be expected unless a testicular product contains far larger amounts of testicular hormone than these preparations can possibly contain in a practical dosage. The firm submits no evidence for the efficacy of these products, and in the absence of other favorable evidence they are unacceptable for New and Nonofficial Remedies

The Council declared Corpus Luteum Solution (Rovin), Kidney Solution (Rovin), Lymphatic Solution (Rovin), Mammary Solution (Rovin), Ovarian Solution (Rovin), Ovarian Residue Solution (Rovin), Thyroid Solution (Rovin), Pituitary Anterior Lobe Solution (Rovin), Suprarenal Gland Solution (Rovin), Suprarenal Cortex Solution (Rovin), Thymus Solution (Rovin), Spleen Solution (Rovin), Spleen Solution 500% (Rovin), Orchic Solution (Rovin), and Prostate Gland Solution (Rovin) unacceptable for New and Nonofficial Remedies because they are products of indefinite composition and of undemonstrated therapeutic value and declared Pituitary Anterior Lobe Sex Hormone Solution (Rovin), Liver Solution (Rovin) and Orchic Extract (Rovin) unacceptable because they are products of undemonstrated therapeutic value.

Committee on Foods

REPORTS OF THE COMMITTEE

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS
RAYMOND HERTWIG, Secretary

NOT ACCEPTABLE

FIG AND BRAN, Bran Plus Sun Ripe Figs

The Battle Creek Food Company, Battle Creek, Mich., submitted to the Committee on Foods a product called "Fig and Bran" prepared from wheat bran, California figs, malt extract, sucrose, wheat germ, salt and an extract of brewers' yeast and vegetables

Analysis (submitted by manufacturer) —

	per cent
Moisture	82
Ash	74
Fat (ether extraction method)	26
Protein (N \times 6.25)	95
Crude fiber	80
Carbohydrates other than crude fiber (by difference)	64.3

Discussion of Name—The name "Fig and Bran," by giving first place to "figs," emphasizes the fig content over that of the bran, thereby connoting that the figs are in greater proportion than is the bran, which is contrary to fact, the bran being in much the greater proportion. The name "Fig and Bran" therefore is misinformative and misleading. "Bran and Figs," giving first place to the predominant ingredient, is an appropriate, correctly informative name for the product.

The company was advised of the Committee's opinion but declines to make the recommended name change on the grounds that such change would be detrimental to the product from a sales standpoint in that past promotional advertising has built up a certain trade acceptance of the present name. This product therefore is not listed among the Committee's accepted foods.

NOT ACCEPTABLE

HOYLAND'S SMA\—ALL OF THE WHEAT TOASTED

The Hoyland Flour Mills Company, Kansas City, Mo., submitted to the Committee on Foods a lightly toasted, coarsely ground wheat with fine flour removed called "Hoyland's Sma\—All of the Wheat Toasted"

Discussion of Label—The following statements appear on the package label: "Sma\ is extremely high in food value and containing all the bran is a natural laxative. Because of its high phosphorus and calcium content—in a natural state—Sma\ makes an ideal food for growing children. Nature's food as nature intended." Whole wheat and cereals are poor providers of calcium nutritional needs. Sma\ therefore "because of its high calcium content" is not "an ideal food for growing children." It is intimated that because the phosphorus and calcium are "in a natural state" they have unique undefined nutritional value. This is an unfounded inference. Calcium claims in public advertising for cereals are misinformative and misleading. Whole wheat is no more "Nature's food" than are other foods, nor is there scientific information that "Nature intended" wheat to be used solely in the form of whole wheat or as "Sma\." The claim is suggestive of current whole wheat food faddism and, although meaningless in fact, is popularly cogent because of its vagueness.

The manufacturer was informed of this opinion but has ignored letters giving the Committee's recommendations. This product, therefore, is not listed among the Committee's accepted foods.

NOT ACCEPTABLE

BUTTERFLY POTATO BREAD

The Geneva Baking Company, New York, submitted to the Committee on Foods a white bread called "Butterfly Potato Bread" prepared from flour, water, a partially hydrolyzed starch, dextrose, salt, lard, powdered skim milk, malt syrup, potato flour, yeast, and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate.

Discussion of Label and Name—The small amount of potato ingredient in the baking formula does not warrant the name "Potato Bread" and facsimiles of potatoes on the label which are indicative of sufficient potato content to give the bread physical, flavor and nutritional characteristics differing essentially from the usual white bread. The name and label, therefore, are considered misinformative and misleading.

The manufacturer was informed of this opinion but has not expressed himself as willing to change the name and label in accordance with the Committee's recommendations. This bread, therefore, is not listed among the Committee's accepted foods.

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary

MARECHAL NEIL FLOUR (BLEACHED) PHOSPHATE ADDED

WHITE BILLOWS FLOUR (BLEACHED) PHOSPHATE ADDED

Manufacturer—Collin County Mill & Elevator Company, McKinney, Texas

Description—"All purpose" patent flours milled from hard and soft wheat and containing 0.5 per cent added calcium acid phosphate, bleached.

Manufacture—Selected wheat is cleaned, washed, scoured and milled by essentially the same procedures as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are blended and bleached with a mixture of benzoyl peroxide and calcium phosphate (1 part to 50,000 parts flour) and with nitrogen trichloride ($\frac{1}{10}$ ounce per barrel). One part of calcium acid phosphate is added to 191 parts flour.

Analysis (submitted by manufacturer) —

	per cent
Moisture	12.0–14.0
Ash	0.77–0.81
Fat (ether extraction method)	0.8–1.0
Protein (N \times 5.7)	9.6–10.0
Crude fiber	0.3–0.4
Carbohydrates other than crude fiber (by difference)	76.5–73.8

Calories—3.5 per gram, 99 per ounce

Claims of Manufacturer—Phosphated patent flours intended especially for biscuit baking.

PANTRY TABLE CREAM (Sterilized)

Manufacturer—S. M. A. Corporation, Cleveland

Description—Canned sterile homogenized cream of 18 per cent milk-fat content.

Manufacture—The cream is removed by a centrifugal separator from pasteurized milk fulfilling the provisions of the sanitary code No. 9 of the Cleveland Board of Health, it is standardized to an 18 per cent milk fat content, is homogenized by being forced under pressure through small apertures, is canned, and processed until sterile.

Analysis (submitted by manufacturer) —

	per cent
Moisture	74.5
Total solids	25.5
Ash	0.6
Fat (ether extract)	18.0
Protein (N \times 6.38)	3.3
Acidity as lactic acid	0.16
Lactose (by difference)	3.4

Calories—1.9 per gram, 54 per ounce

Micro-Organisms—The procedure of manufacture assures a sterile product as shown by the standard methods of bacteriologic analysis of milk of the American Public Health Association.

Vitamins—The vitamin content may be expected to approximate that of the pasteurized cream used.

Claims of Manufacturer—For all table uses of cream.

WHITE BREAD

American Bakers Association Educational Bulletin

Sponsors American Institute of Baking, Chicago

The bulletin in popular language discusses the scientific nutritional values of white bread and its place in the balanced adequate diet. The subject matter is briefly treated under five caption headings

- 1 Is white bread fattening?
- 2 Has white bread been robbed of its minerals?
- 3 Has white bread been robbed of its roughage?
- 4 Is white bread lacking in nutrition?
- 5 Is white bread as wholesome as whole wheat bread?

White bread is essentially a carbohydrate energy food, it contains biologically good quality protein and small proportions of fat and mineral elements, mainly phosphorus and potassium. Milk and skim milk breads contribute significant quantities of calcium also. White bread is not more fattening than are other energy foods, it or other energy foods are essentials of all diets, including reducing diets.

White bread is almost completely digested, its nutrients to like degree, therefore, are available for use by the body. It furnishes little indigestible roughage as compared to whole wheat or bran bread.

Wheat and whole wheat breads are two different types of bread, both are wholesome and nutritious. They may be used interchangeably in the normal diet according to the appeal of palatability. The supplementary food values furnished by whole wheat bread (roughage, iron and vitamin B), which are provided in lesser amounts in white bread, are readily and efficiently furnished by fruits and vegetables, which foods should make up a considerable proportion of all well balanced diets.

The American baker supplies the public with both white bread and whole wheat bread, a decided preference is shown for white bread. There is no justifiable scientific objection to this commercial practice. White bread is an economical source of the energy quota of a complete diet which should contain ample quantities of milk, eggs, meat, fruit and vegetables.

SWEET PEA SELF RISING FLOUR
(BLEACHED)

Manufacturer—Collin County Mill & Elevator Company, McKinney, Texas

Description—A self-rising "stuffed straight" flour containing a blend of flours from hard and soft wheats, calcium acid phosphate, salt and baking soda, bleached.

Manufacture—The ingredients are well mixed in a batch mixer and automatically packed in bags. The flour used is bleached with a mixture of benzoyl peroxide and calcium phosphate (1 part to 50,000 parts of flour) and with nitrogen trichloride ($\frac{1}{2}$ ounce per 196 pounds).

Analysis (submitted by manufacturer) —

	per cent
Moisture	11.0 - 13.0
Ash	3.6 - 4.0
Fat (ether extraction method)	0.9 - 1.2
Protein (N \times 5.7)	9.5 - 10.0
Crude fiber	0.3 - 0.5
Carbohydrates other than crude fiber (by difference)	74.7 - 71.3

Calories—3.4 per gram 97 per ounce.

Claims of Manufacturer—This self-rising flour is specially intended for biscuit baking.

PFIZER GLUCONO-DELTA-LACTONE
(Purified Anhydride of Gluconic Acid)

Manufacturer—Charles Pfizer & Co, Inc, Brooklyn

Description—A purified anhydride of gluconic acid.

Manufacture—The glucono-delta-lactone is prepared by an oxidizing fermentation of dextrose by means of a bacterium which oxidizes the sugar to gluconic acid without any significant formation of other acids. The fermentation is carried out under aerobic conditions. The resulting gluconic acid liquor is concentrated under reduced pressure, cooled and seeded with glucono-delta lactone crystals, and evaporation continued until a substantial crop of glucono-delta-lactone has crystallized out. The crystal crop is separated from the mother liquor by centrifugation washed with cold water and dried by steam

heat. The dried crystals are packed in suitably lined barrels or drums.

Analysis (submitted by manufacturer) —

	per cent
Delta glucono-delta lactone	not less than 99.5
Gluconic acid equivalent	109.6
	Maximum limits of impurities
Residue on ignition	0.1
Gluconic acid anhydrous	trace
Insoluble in water	0.01
Sugars (as d glucose)	0.5
Heavy metals as lead (Pb)	0.002
Iron (Fe)	0.001
Oxalate (C_2O_4)	0.02
Calcium (Ca)	0.05
Sulphate (SO_4)	0.05

Alcohol solubility tests indicate the product to be a delta-lactone and not gamma-lactone.

Alcohol soluble substances are less than 1 per cent.

Sample with acetic anhydride and concentrated sulphuric acid forms crystals of tetra-acetyl gluconic acid monohydrate (melting point 114 C).

Calories—3.5 per gram 99 per ounce. (Calculated from data in International Critical Tables 5:166)

Claims of Manufacturer—An organic acid anhydride for use as an acidulant in foods such as bakery and fruit products, and baking powder. In baking, it gives a retarded evolution of carbon dioxide with baking soda.

HEINZ STRAINED SPINACH

(Already Cooked Without Salt or Sugar)

Manufacturer—H J Heinz Company, Pittsburgh

Description—Canned comminuted and strained cooked spinach retaining in high degree the mineral and vitamin contents of the natural product, no added sugar or salt, the coarser fibrous portion is removed.

Manufacture—The spinach used is grown specially for the Heinz Company, harvested, delivered promptly to the factory, trimmed, thoroughly spray washed and carefully inspected. No blanching process is used, to avoid loss of nutrient material. The clean spinach is drained, placed in a closed cooker the air of which is quickly expelled by steam, and given a light cooking under slight pressure in such a manner as to avoid any loss through leaching or the necessity for adjustment of the consistency of the final comminuted vegetable. The vegetable is removed from the cooker and discharged into a comminution machine, which cuts the vegetable and forces it through a metal plate with coarse perforations. It is then passed through a finishing machine, in which it is forced through a screen of fine perforation. A steam atmosphere surrounds the material during the comminution and sieving process to protect the vitamins and flavors. The coarse material that fails to pass through the fine screen is rejected. The vegetable pulp passing through the screen is collected in glass lined vacuum tanks. When a batch has accumulated, the tank is closed and subjected to a "high vacuum" with gentle agitation to remove dissolved or admixed air. It is filled into enamel lined cans, which are closed under "vacuum" and subjected to adequate heat processing.

Analysis (submitted by manufacturer) —

	per cent
Moisture	93.7
Total solids	6.3
Ash	1.4
Sodium chloride (NaCl)	0.06
Fat (ether extract)	0.5
Protein (N \times 6.25)	2.2
Reducing sugars as invert before inversion	None
Reducing sugars as invert after inversion	None
Sucrose	None
Crude fiber	None
Carbohydrates other than crude fiber (by difference)	0.7
Calcium (Ca)	1.5
Phosphorus (P)	0.057
Iron (Fe)	0.038
	0.001

Calories—0.2 per gram 57 per ounce.

Vitamins—The method of preparation efficiently protects the natural vitamin values. The strained spinach is a rich source of vitamin A and a good source of B, C and G.

Claims of Manufacturer—For table use, but especially intended for infants, children and convalescents and for special smooth diets. Only warming is required for serving. The natural mineral and vitamin values are efficiently retained.

Committee on Foods

REPORTS OF THE COMMITTEE

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS
RAYMOND HERTWIG, Secretary

NOT ACCEPTABLE

FIG AND BRAN, Bran Plus Sun Ripe Figs

The Battle Creek Food Company, Battle Creek, Mich., submitted to the Committee on Foods a product called "Fig and Bran" prepared from wheat bran, California figs, malt extract, sucrose, wheat germ, salt and an extract of brewers' yeast and vegetables

Analysis (submitted by manufacturer) —

	per cent
Moisture	82
Ash	74
Fat (ether extraction method)	26
Protein (N \times 6.25)	95
Crude fiber	80
Carbohydrates other than crude fiber (by difference)	643

Discussion of Name—The name "Fig and Bran," by giving first place to "figs," emphasizes the fig content over that of the bran, thereby connoting that the figs are in greater proportion than is the bran, which is contrary to fact, the bran being in much the greater proportion. The name "Fig and Bran" therefore is misinformative and misleading. "Bran and Figs," giving first place to the predominant ingredient, is an appropriate, correctly informative name for the product.

The company was advised of the Committee's opinion but declines to make the recommended name change on the grounds that such change would be detrimental to the product from a sales standpoint in that past promotional advertising has built up a certain trade acceptance of the present name. This product therefore is not listed among the Committee's accepted foods.

NOT ACCEPTABLE

HOYLAND'S SMA\—ALL OF THE WHEAT TOASTED

The Hoyland Flour Mills Company, Kansas City, Mo., submitted to the Committee on Foods a lightly toasted, coarsely ground wheat with fine flour removed called "Hoyland's Sma\—All of the Wheat Toasted"

Discussion of Label—The following statements appear on the package label: "Sma\ is extremely high in food value and containing all the bran is a natural laxative. Because of its high phosphorus and calcium content—in a natural state—Sma\ makes an ideal food for growing children. Nature's food as nature intended." Whole wheat and cereals are poor providers of calcium nutritional needs. Sma\ therefore "because of its high calcium content" is not "an ideal food for growing children." It is intimated that because the phosphorus and calcium are "in a natural state" they have unique undefined nutritional value. This is an unfounded inference. Calcium claims in public advertising for cereals are misinformative and misleading. Whole wheat is no more "Nature's food" than are other foods, nor is there scientific information that "Nature intended" wheat to be used solely in the form of whole wheat or as "Sma\." The claim is suggestive of current whole wheat food faddism and, although meaningless in fact, is popularly cogent because of its vagueness.

The manufacturer was informed of this opinion but has ignored letters giving the Committee's recommendations. This product, therefore, is not listed among the Committee's accepted foods.

NOT ACCEPTABLE

BUTTERFLY POTATO BREAD

The Geneva Baking Company, New York, submitted to the Committee on Foods a white bread called "Butterfly Potato Bread" prepared from flour, water, a partially hydrolyzed starch, dextrose, salt, lard, powdered skim milk, malt syrup, potato flour, yeast, and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate.

Discussion of Label and Name—The small amount of potato ingredient in the baking formula does not warrant the name "Potato Bread" and facsimiles of potatoes on the label which are indicative of sufficient potato content to give the bread physical, flavor and nutritional characteristics differing essentially from the usual white bread. The name and label, therefore, are considered misinformative and misleading.

The manufacturer was informed of this opinion but has not expressed himself as willing to change the name and label in accordance with the Committee's recommendations. This bread, therefore, is not listed among the Committee's accepted foods.

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary

MARECHAL NEIL FLOUR (BLEACHED) PHOSPHATE ADDED WHITE BILLOWS FLOUR (BLEACHED) PHOSPHATE ADDED

Manufacturer—Collin County Mill & Elevator Company, McKinney, Texas

Description—"All purpose" patent flours milled from hard and soft wheat and containing 0.5 per cent added calcium acid phosphate, bleached.

Manufacture—Selected wheat is cleaned, washed, scoured and milled by essentially the same procedures as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are blended and bleached with a mixture of benzoyl peroxide and calcium phosphate (1 part to 50,000 parts flour) and with nitrogen trichloride ($\frac{1}{2}$ ounce per barrel). One part of calcium acid phosphate is added to 191 parts flour.

Analysis (submitted by manufacturer) —

	per cent
Moisture	12.0–14.0
Ash	0.77–0.81
Fat (ether extraction method)	0.8–1.0
Protein (N \times 5.7)	9.6–10.0
Crude fiber	0.3–0.4
Carbohydrates other than crude fiber (by difference)	76.5–73.8

Calories—35 per gram, 99 per ounce

Claims of Manufacturer—Phosphated patent flours intended especially for biscuit baking.

PANTRY TABLE CREAM (Sterilized)

Manufacturer—S. M. A. Corporation, Cleveland

Description—Canned sterile homogenized cream of 18 per cent milk-fat content.

Manufacture—The cream is removed by a centrifugal separator from pasteurized milk fulfilling the provisions of the sanitary code No. 9 of the Cleveland Board of Health, it is standardized to an 18 per cent milk fat content, is homogenized by being forced under pressure through small apertures, is canned, and processed until sterile.

Analysis (submitted by manufacturer) —

	per cent
Moisture	74.5
Total solids	25.5
Ash	0.6
Fat (ether extract)	18.0
Protein (N \times 6.38)	3.3
Acidity as lactic acid	0.16
Lactose (by difference)	3.4

Calories—19 per gram, 54 per ounce.

Micro-Organisms—The procedure of manufacture assures a sterile product as shown by the standard methods of bacteriologic analysis of milk of the American Public Health Association.

Vitamins—The vitamin content may be expected to approximate that of the pasteurized cream used.

Claims of Manufacturer—For all table uses of cream.

WHITE BREAD

American Bakers Association Educational Bulletin

Sponsors American Institute of Baking, Chicago

The bulletin in popular language discusses the scientific nutritional values of white bread and its place in the balanced adequate diet. The subject matter is briefly treated under five caption headings

- 1 Is white bread fattening?
- 2 Has white bread been robbed of its minerals?
- 3 Has white bread been robbed of its roughage?
- 4 Is white bread lacking in nutrition?
- 5 Is white bread as wholesome as whole wheat bread?

White bread is essentially a carbohydrate energy food, it contains biologically good quality protein and small proportions of fat and mineral elements, mainly phosphorus and potassium. Milk and skim milk breads contribute significant quantities of calcium also. White bread is not more fattening than are other energy foods, it or other energy foods are essentials of all diets, including reducing diets.

White bread is almost completely digested, its nutrients to like degree, therefore, are available for use by the body. It furnishes little indigestible roughage as compared to whole wheat or bran bread.

Wheat and whole wheat breads are two different types of bread, both are wholesome and nutritious. They may be used interchangeably in the normal diet according to the appeal of palatability. The supplementary food values furnished by whole wheat bread (roughage, iron and vitamin B), which are provided in lesser amounts in white bread, are readily and efficiently furnished by fruits and vegetables, which foods should make up a considerable proportion of all well balanced diets.

The American baker supplies the public with both white bread and whole wheat bread, a decided preference is shown for white bread. There is no justifiable scientific objection to this commercial practice. White bread is an economical source of the energy quota of a complete diet which should contain ample quantities of milk, eggs, meat, fruit and vegetables.

SWEET PEA SELF RISING FLOUR
(BLEACHED)

Manufacturer—Collin County Mill & Elevator Company, McKinney, Texas

Description—A self-rising "stuffed straight" flour containing a blend of flours from hard and soft wheats, calcium acid phosphate salt and baking soda, bleached.

Manufacture—The ingredients are well mixed in a batch mixer and automatically packed in bags. The flour used is bleached with a mixture of benzoyl peroxide and calcium phosphate (1 part to 50 000 parts of flour) and with nitrogen trichloride ($\frac{1}{10}$ ounce per 196 pounds).

Analysis (submitted by manufacturer) —

Moisture	per cent
Ash	11.0 - 13.0
Fat (ether extraction method)	3.6 - 4.0
Protein (N \times 5.7)	0.9 - 1.2
Crude fiber	9.5 - 10.0
Carbohydrates other than crude fiber (by difference)	0.3 - 0.5
	74.7 - 71.3

Calories—3.4 per gram 97 per ounce.

Claims of Manufacturer—This self-rising flour is specially intended for biscuit baking.

PFIZER GLUCONO-DELTA-LACTONE
(Purified Anhydride of Gluconic Acid)

Manufacturer—Charles Pfizer & Co., Inc., Brooklyn

Description—A purified anhydride of gluconic acid.

Manufacture—The glucono-delta-lactone is prepared by an oxidizing fermentation of dextrose by means of a bacterium which oxidizes the sugar to gluconic acid without any significant formation of other acids. The fermentation is carried out under aerobic conditions. The resulting gluconic acid liquor is concentrated under reduced pressure, cooled and seeded with glucono delta lactone crystals, and evaporation continued until a substantial crop of glucono-delta-lactone has crystallized out. The crystal crop is separated from the mother liquor by centrifugation, washed with cold water and dried by steam

heat. The dried crystals are packed in suitably lined barrels or drums.

Analysis (submitted by manufacturer) —

Delta glucono-delta lactone	per cent
Gluconic acid equivalent	not less than 99.5
	109.6
	Maximum limits of impurities
Residue on ignition	0.1
Gluconic acid anhydrous	trace
Insoluble in water	0.01
Sugars (as <i>d</i> glucose)	0.5
Heavy metals as lead (Pb)	0.002
Iron (Fe)	0.001
Oxalate (C_2O_4)	0.02
Calcium (Ca)	0.05
Sulphate (SO_4)	0.05

Alcohol solubility tests indicate the product to be a delta-lactone and not gamma-lactone.

Alcohol soluble substances are less than 1 per cent.

Sample with acetic anhydride and concentrated sulphuric acid forms crystals of tetra-acetyl gluconic acid monohydrate (melting point 114 C.).

Calories—3.5 per gram 99 per ounce. (Calculated from data in International Critical Tables 5:166.)

Claims of Manufacturer—An organic acid anhydride for use as an acidulant in foods such as bakery and fruit products, and baking powder. In baking, it gives a retarded evolution of carbon dioxide with baking soda.

HEINZ STRAINED SPINACH

(Already Cooked Without Salt or Sugar)

Manufacturer—H. J. Heinz Company, Pittsburgh

Description—Canned comminuted and strained cooked spinach retaining in high degree the mineral and vitamin contents of the natural product, no added sugar or salt, the coarser fibrous portion is removed.

Manufacture—The spinach used is grown specially for the Heinz Company, harvested, delivered promptly to the factory, trimmed, thoroughly spray washed and carefully inspected. No blanching process is used, to avoid loss of nutrient material. The clean spinach is drained, placed in a closed cooker the air of which is quickly expelled by steam, and given a light cooking under slight pressure in such a manner as to avoid any loss through leaching or the necessity for adjustment of the consistency of the final comminuted vegetable. The vegetable is removed from the cooker and discharged into a comminution machine, which cuts the vegetable and forces it through a metal plate with coarse perforations. It is then passed through a finishing machine, in which it is forced through a screen of fine perforation. A steam atmosphere surrounds the material during the comminution and sieving process to protect the vitamins and flavors. The coarse material that fails to pass through the fine screen is rejected. The vegetable pulp passing through the screen is collected in glass lined vacuum tanks. When a batch has accumulated, the tank is closed and subjected to a "high vacuum" with gentle agitation to remove dissolved or admixed air. It is filled into enamel lined cans, which are closed under "vacuum" and subjected to adequate heat processing.

Analysis (submitted by manufacturer) —

Moisture	per cent
Total solids	93.7
Ash	6.3

THE EFFECTS OF EXERCISE

The evolution of a mechanized society, about which so much is heard at the present time, has brought about changes in the physiologic functions of the man of today as well as in his economic relationships. Hard physical work, once the lot of the majority of people, is gradually being relegated into the category of the less usual experiences of daily life. As a consequence the bodily conditions formerly resulting so largely from muscular work as a part of the customary routine of living are now being developed through voluntary exercise and athletics. It has been stated¹ that athletics consist of physical exercise plus more or less of emotional exercise, while work is likely to involve less and less of the emotions.

A modicum of muscular effort—of work—has always been regarded as wholesome to the healthy organism. There is a widespread belief that certain physiologic advantages and desirable bodily changes are attributable to physical exercises and training. How real are they, and what is their nature? An elaborate discussion of these questions has recently been presented by Steinhaus¹ of the Young Men's Christian Association College of Chicago. As he points out, increases in muscle size, strength and endurance are probably among the best recognized chronic effects of muscular exertion. One cannot proceed far in the consideration of the contractile tissues without being brought face to face with the problems of their blood supply, for through this the removal of waste and the replenishment of energy alone can be insured. The interrelationship between the skeletal muscles and the circulatory apparatus seems to have been recognized by the discoverer of the circulation of the blood. In 1628, Harvey wrote "The more muscular and powerful men are, the firmer their flesh, the stronger, thicker, denser and more fibrous their hearts, the thicker, closer and stronger are the auricles and arteries." Haldane once remarked that the circulation and respiration may be looked on

as the servants of the muscles. Today there are added factors that call for recognition: chemical changes in the blood, adjustments of the respiratory functions, involvements of the endocrine organs, and new coordinations in the nervous system. It has been stated that undoubtedly the greatest and most lasting changes induced by training in man and animal, namely, changes in behavior, take place in the nervous system.

If the thesis that exercise increases the capacity of the organism to perform work is accepted, it becomes interesting to consider the "interlocking division of responsibilities" for this general outcome. The physiologist Lindhard² recognizes improvements in strength, in endurance and in sureness of perfection of movement, and he attributes them in general to changes in the muscular system, respirocirculatory system and nervous system, respectively.

According to Steinhaus, increase in strength is no doubt primarily associated with the hypertrophy of muscle in which largely the sarcoplasm participates. Too little is known of the way in which chemical energy is transformed into mechanical energy in the muscle to speculate on how the chemical changes observed in muscle contribute to the increase of strength. Endurance, or the postponement of fatigue, is a measure of the organism's ability to balance catabolic with appropriate anabolic processes. Primarily this means a sufficient supply of oxygen and, secondarily, a food supply. The modern conception of the chemical details involved in muscle mechanics is sufficiently novel to warrant repetition here. Phosphocreatine, a recently recognized muscle component, is broken down and then resynthesized at the expense of a glycolytic process. Steinhaus postulated the following possible causes of fatigue: (1) Depletion of the phosphocreatine store, as by loss of one or both of its breakdown products. (2) Failure of the resynthesis process as the result of some limitation being set on the production of lactic acid, which most commonly is probably due to the accumulation of lactic acid and therefore to (3) inability to oxidize lactic acid promptly because of a shortage of oxygen. The lactic acid thus accumulated enters the circulation and causes (4) disturbances in carbon dioxide carrying power of the blood, in the respiratory center and in vasomotor regulation, which an increased circulation can only temporarily compensate. (5) Failure of the circulatory and respiratory system to meet these demands.

The various adaptations that facilitate the performance of more exercise and result from a period of "training" bring about increased return of venous blood by active muscles to the heart. This organ is filled more completely, an outcome which, in accord with the "law of the heart," induces stronger systoles. Oft repeated, as Steinhaus points out, this leads to cardiac hypertrophy with corresponding greater stroke volume,

¹ Steinhaus, A. H. Chronic Effects of Exercise, *Physiol Rev* 13: 103 (Jan) 1933.

² Lindhard, J. *Ergebn d Physiol* 33: 337 1931.

resting minute volume, and slower pulse rate. The faster circulation of the blood results in fragmentation of older corpuscles, both red and white, and a consequent stimulation of the corpuscle-producing tissues. The blood corpuscles are thus "trimmed" for greater service. A greater resting minute volume, augmented by the return flow as soon as exercise begins, carries much greater supplies of oxygen to the active tissues, thus providing for the disposition of lactic acid at its source and preventing its entering the circulation in quantities large enough to disturb the equilibrium elsewhere. To bring about the many cardiac, vasomotor and respiratory adjustments a great burden is placed on the nervous system, particularly the autonomic portions. Undoubtedly during exercise these adjustments are mainly due to sympathetic activity. A well ordered program of athletics should aim to elicit gradually these many beneficial reactions without forcing them to the point of detrimental overstrain.

COBALT AND NUTRITION

Effort expended with one objective in view often proves important in a different and frequently unforeseen direction. The possibility for such a circumstance is greater, the more complex the system to which the initial adjustment is applied. In the history of the development of biochemistry, many cases in point have arisen. An instance in which this principle is generally applicable is the possible clinical significance of the data derived from the many recent serious investigations of nutritional anemia. These studies have been largely on experimental animals, whether nutritional anemia in animals has a counterpart in human anemias is a question that has not been definitely answered. However, disappointing as it may seem that the results from experimental anemia are difficult to translate into clinical experience, they have served the unsought purpose of stimulating interest in several unusual chemical elements the nutritional significance of which has not heretofore been fully appreciated. Among these is cobalt.

The present revival of interest in cobalt dates from the observation of the Walters¹ that administration of this metal produces a polycythemia in experimental animals. The nature of this response has been studied further by Orten, Underhill, Mugrage and Lewis.² It appears that, with a ration of fluid milk to which iron and copper have been added, a polycythemia is produced when cobalt is added. This is characterized by an increase in both erythrocytes and pigment, it does not take place, however, in the absence of copper. Furthermore, when cobalt is added to a milk-iron-copper diet, the total volume of the blood is increased, this change being conditioned by the augmented cell volume rather

than by a variation in amount of plasma. It had been shown previously¹ that cobalt is toxic in small daily doses. The Colorado investigators have demonstrated that the retardation of growth and the toxicity of cobalt are somewhat alleviated by the inclusion of manganese in the experimental ration. Furthermore, the high concentration of hemoglobin, the augmented number of erythrocytes and the increased blood volume produced by cobalt were more steadily maintained throughout the experimental period when manganese was present.

The daily quantity of cobalt required to bring about these striking blood responses in animals is extremely small, from 0.1 to 0.5 mg. In attempting to discover the mechanism whereby the typical reaction is produced, it is of some importance to know the organs and tissues in which the cobalt is localized after its administration. In a recent contribution of Stare and Elvehjem³ it is pointed out that cobalt, if it occurs in biologic substances, does so in extremely small amounts, for, within the limits of accuracy of the analytic method employed, they could not demonstrate any cobalt in the entire body of albino rats maintained on a diet of milk to which iron, copper and manganese were added. When cobalt was added to this ration minute amounts were detected, roughly proportional to the quantities fed. When cobalt is fed it appears to become localized in the liver, pancreas and spleen, though the absolute amounts retained are extremely small.

These observations on cobalt, an element which as recently as five years ago was doubtless looked on as a biochemical novelty, emphasize again the importance of what Mendel has referred to as the "little things" in the diet. It has been shown³ that 0.04 mg of cobalt in the entire body of an albino rat weighing 150 Gm is sufficient to produce a striking polycythemia. Observations such as these have served to alter the entire point of view in one branch of the science of nutrition. Recurring demonstrations of the biochemical significance of mere traces of commonly disregarded substances serve as well as do metaphyses to illustrate how exquisitely the organism is adjusted to its environment.

PROGRESS OF MEDICINAL LIQUOR LEGISLATION

The medicinal liquor bill sponsored by the American Medical Association was reported to the House of Representatives by the Committee on the Judiciary, February 15, with a recommendation that it pass.¹ The bill may now come before the House for action at any time. If it passes the House, however, as it seems likely to do, it must still run the gantlet of the Senate.

This bill, if enacted, will do away with the quantitative limits on the medical use of alcohol and on the

¹ Walters, Clara and Walter, Karl. *Klin. Wchnschr.* 5: 313 (Feb. 12) 1926.
² Orten, J. M., Underhill, F. M., Mugrage, E. R. and Lewis, J. C. *J. R. I. Chem.* 36: 11 (April) 1930. 39: 4 (Jan.) 1933.

³ Stare, F. J. and Elvehjem, C. A. *J. Biol. Chem.* 99: 473 (Jan.) 1934.
¹ H. R. 14595. H. R. Report No. 2044.

issue of prescriptions, now arbitrarily fixed by the National Prohibition Act. It will substitute for them the simple formula, "no more liquor shall be prescribed to any person than is necessary to supply his medical needs." To safeguard against the possible abuse of the right to prescribe liquor, the bill provides that the Attorney General and the Secretary of the Treasury jointly may promulgate regulations with reference to the quantities of liquor that may be prescribed for medicinal purposes. The regulations formulated in this way can be based on medical evidence and on the experience of the officers charged with the enforcement of the law. If the regulations prove to be unnecessarily severe or fail to prevent the diversion of medicinal liquor to beverage purposes, they can easily be modified from time to time in the light of experience. Thus regulations may finally be developed that permit the rational use of liquor for medical purposes, with as few obstacles as are consistent with the effective enforcement of the provisions of the law forbidding the manufacture and sale of liquor as a beverage.

The disclosure of the nature of the illness from which a patient is suffering, in records filed with the Bureau of Industrial Alcohol, is not now required. A legal prohibition of demands for such disclosures is proposed by this bill, however, to prevent future demands for disclosures of this character. The bill provides that no physician shall be called on to file any statement of his patient's ailment in the Department of Justice, the Department of the Treasury or any other office of the government, or to keep his records in a way that may lead to the disclosure of any such ailment. A physician is to be required to make only such disclosures as are called for in court or in the course of proceedings looking toward the revocation of a permit issued under the National Prohibition Act or as are necessary to enable an officer charged with the execution and enforcement of the act to perform his duty.

The third change proposed by this bill is the abolition of the cumbersome and costly official prescription blanks now in use. Physicians are to use their own prescription blanks. To prevent prescribing by unauthorized persons, the Treasury Department is to issue stamps, free of cost, to physicians holding permits to prescribe, and the physician is to affix such a stamp to each prescription for liquor and to cancel the stamp thus affixed. A prescription for liquor, without a canceled stamp, is to be void. The use of stamps, instead of the present official prescription blanks, will save the government considerably more than \$100,000 a year and will probably save the physicians of the country time, trouble and annoyance that now cost them several times that amount.

The bill as it now stands represents, it is believed, the best that can be done toward removing the grievances of physicians against present methods. No opposition to the bill has been heard from any quarter. The

absence of opposition, however, is not in itself sufficient to insure the enactment of the bill, there must be an affirmative demand for enactment. If the medical profession of the country desires that this bill be enacted during the current session of Congress, individual physicians and organized groups must urge their Senators to vote for it. Even if local laws in any state are such as prevent prescribing of alcoholic liquors, the medical profession of the state should nevertheless voice its demand for its enactment in the interest of the patients of their confreres in other states.

Only a few days remain before March 4, when the present Congress expires. What is done must be done quickly. Telegrams, or letters by air mail, special delivery or air mail plus special delivery should therefore be used in forwarding requests for the enactment of this legislation.

Current Comment

ADVERTISING BEGINS TO CLEAN HOUSE

Announcement is made in a recent issue of *Printers' Ink* of the establishment, within the advertising industry itself, of a permanent review committee, which is to operate as a court of appeals. The committee is an outgrowth of a movement begun in May, 1932, to develop a code to control advertising practices in order to prevent a continuing trend toward the discrediting of all advertising. The plans of the permanent committee, which is at this time headed by Ralph Starr Butler, representing the Association of National Advertisers, and himself advertising manager for General Foods Corporation, involve the development of a code and of methods for handling violations of the code. Already the code drawn up includes seven points that tend to discredit advertising. These are

- 1 False statements or misleading exaggerations
- 2 Indirect misrepresentation of a product or service through distortion of details, either editorially or pictorially
- 3 Statements or suggestions offensive to public decency
- 4 Statements which tend to undermine an industry by attributing to its products, generally, faults and weaknesses true only of a few
- 5 Price claims that are misleading
- 6 Pseudoscientific advertising, including claims insufficiently supported by accepted authority or that distort the true meaning or application of a statement made by professional or scientific authority
- 7 Testimonials which do not reflect the real choice of a competent witness

It is interesting to find that advertising has at last begun to realize the menace inherent in many current advertising practices, and that it is doing the best thing possible under the circumstances, namely, cleaning its own house. It has been the pride of organized medicine that it invariably cleans its own house. It is to be hoped that this movement in the field of advertising, begun under such excellent auspices, will lead to much needed reforms.

**COMBINED LOCAL AND SYSTEMIC
SPECIFIC THERAPY**

The difficulties of controlling "carrier" conditions have recently been emphasized in a statement by Neufeld and Ettinger-Tulczynska¹ of the Robert Koch Institute, Berlin. The German investigators found that they could produce carrier conditions in mice and guinea-pigs by the nasal instillation of type pneumococci. The majority of the animals did not show signs of systemic infection but became month-long carriers of nasal pneumococci. Contrary to expectations the investigators found that previous active or passive immunization against the same types of pneumococci, although effective in preventing the occasional generalized infection, was without demonstrable prophylactic effects against the development and duration of the carrier states. The carrier condition in itself never led to the development of a sufficient degree of systemic immunity to protect against subsequent intraperitoneal injection with as little as 2 minimum lethal doses of homologous type pneumococci. Consistent with these results, the investigators found that intraperitoneal injections of high titer antipneumococcic serum were not effective in clearing up the carrier condition. Repeated nasal washings with the same antiserum were also not effective, even though the washings were repeated at twelve hour intervals for more than a week. A combination of a single intraperitoneal high-titer antiserum injection with two local antiserum washings, however, was effective. In most cases the combined local and systemic specific therapy led to a complete and permanent specific sterility of the nasal mucosa.

MEDICAL INSPECTION OF ALIENS

During the last fiscal year, medical officers of the U S Public Health Service examined 373,034 alien passengers in order to detect physical or mental conditions as provided for by the immigration laws. In summaries of these examinations, published in the annual report of the Public Health Service,¹ the number and character of the more serious conditions found in these aliens are tabulated. It appears that the medical examiners at various United States ports diagnosed 96 cases of idiocy, imbecility and feeble-mindedness among the alien passengers, 40 cases of epilepsy, 85 of insanity, 118 of psychopathic inferiority, 27 of chronic alcoholism, 119 of tuberculosis, 346 of trachoma, 273 of syphilis, 394 of gonorrhea, 48 of favus, 31 of soft chancre, and 42 cases of other dangerous or loathsome contagious diseases, a total of 1,619 whose physical condition made their exclusion from the United States mandatory. Should this heterogeneous crowd of idiots, imbeciles, epileptics, alcoholic addicts and others have been permitted to enter the United States, it would be impossible to estimate the amount of crime, misery and disease for which they would be responsible. There are now in the asylums, hospitals and jails of the United States far too many inmates whose difficulties could be traced to disease conditions that existed prior to their entry into the country.

Association News**MEDICAL BROADCAST FOR THE WEEK****American Medical Association Health Talks**

The American Medical Association broadcasts on Monday and Wednesday from 9 45 to 9 50 a m (central standard time) over Station WBBM (770 kilocycles, or 389.4 meters).

The subjects for the week are as follows:

February 27 Temper Tantrums.

March 1 Athlete's Foot.

There is also a fifteen minute talk sponsored by the Association on Saturday morning from 9 45 to 10 o'clock over Station WBBM.

March 4 No broadcast.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARIZONA

Bills Introduced—S 94 proposes to authorize the board of medical examiners to license persons to practice chiroprody, which the bill defines as the examination, diagnosis or treatment medically, mechanically or surgically of the ailments of the human foot. However, such licentiates are not to have the right to amputate the toes or joints thereof, or any portion of the foot, or to sever any tendon, or to use any anesthetic other than local. H 165 proposes that the nursing services to be rendered in public welfare institutions be rendered only by registered nurses.

ARKANSAS

Bill Introduced—H 410 proposes a new workmen's compensation act. Occupational diseases are not to be compensable. Employers must provide such medical treatment as their injured employees may require during sixty days after the injury or for such time in excess thereof as the state industrial commission shall order. Employees are not to be allowed to select their own physicians.

CALIFORNIA

Study of the Common Cold—The University of California Medical School, San Francisco, is conducting a study of the factors other than infectious agents that may be concerned in the production of the common cold. In a specially constructed room which accommodates five persons, temperature and humidity can be varied to reproduce extreme conditions or can be kept constant for an indefinite period. Susceptible persons are kept in the room for an incubation period of four or five days, when some one who is suffering with a fresh cold in the head is introduced. Such factors as fatigue and over-eating have been removed. Drs William J Kerr, professor of medicine, and John B Lagen, research assistant are conducting the study.

Bills Introduced—S 953 proposes to create a state board of regulation of hospital associations which is to be authorized to license persons, associations or corporations to engage in the business of issuing contracts for furnishing medical, hospital, nursing or dental services. Exempted from the provisions of the bill are certain types of fraternal societies offering these services to its members. A 1740 proposes a self-styled "chiropractic institutional act." It seeks to require the state board of prison directors to appoint to every institution under its jurisdiction one or more chiropractors. The bill also proposes that chiropractors be given the right to practice within the confines of every hospital or other institution receiving workmen's compensation from the state. A 1739 to amend the chiropractors to render the medical treatment which employers are required to supply to injured employees. A 1813 proposes to abolish the department of professional and vocational standards and to refer to the board of medical examiners all the

January 9 Dr Frederick J Farnell, chairman of the public welfare commission of Rhode Island, gave an address at the hospital, January 30, on "The Autonomic Nervous System and Its Disorders"

Society News—Dr Daniel F Jones, Boston, addressed the Providence Medical Association, January 2, on "Diagnosis and Treatment of Carcinoma of the Colon and Rectum" The society was addressed, February 6, by Drs Frank S Hale and Marco A M Castallo, Providence, on "Voluntary Sex Determination" and "Treatment of Endocervicitis," respectively—Dr Herman A Lawson, Providence, discussed local manifestations of some general systemic diseases before the Rhode Island Ophthalmological and Otological Society, Dec 8, 1932

SOUTH DAKOTA

Bill Introduced—H 153, to amend the medical practice act, proposes to license without examination any physician who is a graduate of a three or four year course in an approved medical college and who has had ten years or more of licensed practice

TEXAS

Bills Introduced—S 212 proposes to repeal the laws regulating the possession and distribution of narcotic drugs and to enact the uniform narcotic drug act H 434 proposes to create a board of chiropractic examiners and to regulate the practice of chiropractic Chiropractic is defined as the "Science of health in anatomical relation, and disease in or from anatomical disrelation The Science of Chiropractic locates and removes pressure on nerves and its effects as the cause of mental and physical disease, disorder or deformity without the use of drugs or operative surgery" Licentiatees are to be permitted to practice chiropractic as thus defined, to have the right to sign death certificates and, apparently, to practice within the confines of public hospitals

Graduate Meeting in San Antonio—The Fifth District Medical Association held its first series of graduate lectures in San Antonio, January 10-12 General sessions were held each morning and afternoon and section meetings for various specialties were held at luncheons It is planned to make this type of meeting an annual affair, with special emphasis on the participation of Mexican physicians Among the lecturers were

Dr William F Braasch, Rochester, Minn., Treatment of Infections of the Urinary Tract
Dr Francisco P Miranda, Mexico City, Cardiac Insufficiency
Dr William Thornwall Davis, Washington, D C, Modern Conception and Treatment of Convergent Squint
Dr Russell L Haden, Cleveland, Chronic Arthritis
Drs Francisco R Vargas and Luis B Soto, Mexico City, Present State of the Mexican Investigation of Typhus Fever
Dr Gabriel Tucker, Philadelphia, Cancer of the Larynx
Dr Rudolph Matas, New Orleans, Blood Vessel Surgery
Dr Leon Bloch, Chicago, Clinical Observations on Ulcer and Discussion of Treatment

Dr Edward H Cary, Dallas, President of the American Medical Association, addressed an evening session on medical economics Dr Sam E Thompson, Kerrville, is president of the fifth district association

WASHINGTON

Bills Introduced—S 113 proposes to repeal chapter 36 Session Laws of 1919, regulating the practice of drugless therapeutics S 200, to amend the workmen's compensation act, proposes to permit osteopaths, chiropractors and other cult practitioners to render the medical treatment required under the act to be furnished injured employees Substitute S 13 proposes to repeal the laws regulating the possession and distribution of narcotic drugs and to enact the uniform narcotic drug act S 201 proposes to create a board of physio-medical examiners and to regulate the practice of physio-medicine and surgery Licentiatees must confine themselves to the principles and philosophy of physio-medicine, which, the bill states, is "that system of medical practice which uses only organic materials and substances or derivatives therefrom for internal administration according to the philosophy of recognized physio-medical colleges" H 265, to amend the optometry practice act proposes (1) to define the practice of optometry as "the employment of any means or methods other than the use of drugs in the diagnosis of any optical deficiency or deformity, visual or muscular anomaly of the human eye, or fitting of glasses, or the prescription of lenses, prisms, or ocular treatment for the correction or relief of the same" and (2) to prohibit licentiatees from using the title "doctor," or any abbreviation thereof without the qualification "optometrist" or the abbreviation O D or "Opt D"

WEST VIRGINIA

Bill Introduced—H 248 proposes to require applicants for marriage licenses to present certificates from licensed physicians stating that the parties to the proposed marriages are free from venereal diseases

WISCONSIN

Society News—Drs Andre Crotti, Columbus, Ohio, and Harry E Mock, Chicago, addressed the Fond du Lac County Medical Society, Fond du Lac, Dec 14, 1932, on "Diseases of the Thyroid and Thymus Glands" and "Treatment of Skull Fractures and Concomitant Injuries," respectively—Dr Matthew N Federspiel, Milwaukee, addressed a joint meeting of the Manitowoc County medical and dental societies in December, on "Diseases and Deformities of the Mouth, Nose and Face"—Drs Samuel J Pearlman and Samuel Salinger, Chicago, presented papers before the Racine County Medical Society, Racine, Dec 15, 1932, on diagnosis of types of nris-toiditis and emergencies in conditions of the ear, nose and throat, respectively

Bills Introduced—A 247 authorizes either spouse to sue for divorce when the other spouse has been an inmate of a hospital for the insane for ten years S 139, to amend the provisions of the medical practice act limiting licenses to practice medicine and surgery or osteopathy and surgery to United States citizens or to persons who have first citizenship papers, proposes that any applicant who by reason of his nationality is not eligible to citizenship and who is a graduate of a reputable professional college in this country prior to the taking effect of this section may be licensed if at least one of his parents shall have been a native of the state A 275 proposes to constitute the state health officer, the secretary of the board of medical examiners and the attorney general a state medical grievance committee to investigate, hear and pass on professional practices by persons licensed to practice medicine and surgery S 169, to amend the workmen's compensation act, proposes to permit injured employees to choose their attending physicians and the hospitals in which they are to be treated If employees fail to exercise their choice of physicians or hospitals, the county medical society of the county in which they are injured is to select the attending physicians from its membership The bill proposes to make it the duty of employers to notify the county medical society immediately after every industrial injury S 172, to amend the medical practice act, proposes to eliminate that provision which exempts from the operation of the act "the practice of Christian Science, or any person who administers to or treats the sick or suffering by mental or spiritual means" The bill proposes, however, that the act shall not be construed to interfere with "consolation or mental or physical benefit gained by religious service or prayer by any person belonging to any religious organization" Any person selecting such treatment is not to be compelled to submit to any medical treatment except in the case of infectious disease or where he is in imminent danger of loss of life Persons administering religious consolation to the sick are not to derive any pecuniary benefit from their practices

WYOMING

Bills Introduced—S 112, to amend the workmen's compensation act, proposes that an employee claiming compensation for an industrial hernia must prove that the hernia is of recent origin, that its appearance was accompanied by pain, that it was immediately preceded by some accidental strain suffered in the course of the employment, and that it did not exist prior to the date of the alleged injury H 272, to amend the medical practice act, proposes that the board of medical examiners consist of "four regularly licensed physicians and one regularly licensed osteopathic physician"

GENERAL

Publication for Health Officers—The *Health Officers' World* made its initial appearance with the January issue It will be published four times a year as the official journal of the International Society of Medical Health Officers Dr John P Koehler, commissioner of health of Milwaukee, is the editor The new journal replaces the *Medical Health Officer* which was published in mimeographed form

Jacobi Fellowship Offered—The Women's Medical Association of New York City offers the Mary Putnam Jacobi Fellowship of \$1000 for one year to women physicians Applications for 1933-1934 should be sent before April 1 to Dr Annie S Daniel, 105 East Fifteenth Street, New York They must be accompanied by statements as to health, educational qualifications and the problem proposed for investigation

tion Two reports are required, one at the end of six months and the second at the end of the year The fellowship is open to any woman graduate of an approved medical school

Officers of Orthopedic Societies—At the first annual meeting of the American Academy of Orthopedic Surgeons in Chicago, January 12, the following officers were elected Drs Willis C Campbell, Memphis, Tenn, president, Philip D Wilson, Boston, vice president, Philip Lewin, Chicago, secretary, and Eugene B Mumford, Indianapolis, treasurer Officers of the Clinical Orthopedic Society elected at its meeting held at the same time are Dr Rexford Diveley, Kansas City, Mo, president, Dr Mumford, vice president, and Dr James E M Thomson, Lincoln, Neb, secretary The next meeting of the Clinical Orthopedic Society will be held in St. Paul, Minneapolis and Rochester, Minn

Dr Henry F Osborn Resigns—Henry Fairfield Osborn, Ph.D., since 1910 research professor of zoology, Columbia University, New York, retired as president of the American Museum of Natural History, January 10 after serving twenty-five years in that capacity Mr F Trubee Davison, assistant secretary of war in charge of aeronautics, Washington, D C, was elected to succeed Professor Osborn, who has been chosen honorary president Professor Osborn's extensive experience has included the teaching of comparative anatomy, biology and zoology at Princeton and Columbia universities At one time he was dean of the faculty of pure science at Columbia He is the author of a large number of books and articles, many of which deal with organic evolution

Southeastern Surgeons to Meet—The Southeastern Surgical Congress will hold its fourth annual assembly at the Atlanta Biltmore Hotel, Atlanta, Ga, March 6-8 Among speakers announced on a preliminary program are

Dr George W Crile Cleveland Peptic Ulcer
Dr Chevalier Jackson Philadelphia Diverticula of the Esophagus and Hypopharynx
Dr William E Lower Cleveland Functions of the Testes
Dr Hubert A Royster Raleigh Pathology of Appendicitis
Dr Edward W A Ochsner New Orleans Relative Value of Sclerosing Agents in the Treatment of Varicose Veins
Dr Dean Lewis Baltimore President Elect American Medical Association Muscle Nerve and Blood Vessel Injuries of the Extremities
Dr Carl A Hedblom Chicago Diagnosis and Treatment of Tumors of the Thorax
Dr William Wayne Babcock Philadelphia The Vaginal Approach to the Peritoneum
Dr Curtice Rosser Dallas Texas Problems Confronting the Proctologist
Dr Irvin Abell Louisville Ky Tumors of the Breast

Medical Bills in Congress—*Changes in Status* H R 7518 has passed both the House and the Senate, empowering the President, under such regulations as he may prescribe, to authorize the board of health of the Canal Zone to issue and revoke licenses to practice the healing art H R 12843 has been favorably reported to the House, without amendment changing the name of the retail liquor dealers stamp tax in the case of retail drug stores or pharmacies (Report No 2038) H R 14395 relating to the prescribing of medicinal liquor has been favorably reported to the House without amendment (Report No 2044) The House Committee on Rules has reported a special rule on the bill which assures early consideration of it *Bills Introduced* S 5624 introduced by Senator Smoot Utah provides that hereafter no disability allowance compensation or hospitalization shall be paid or granted by the Veterans Administration to any World War veteran who did not actually suffer an injury or contract a disease in line of duty as a result of, and directly attributable to service between April 6 1917 and July 2, 1921 H R 14655, introduced by Representative Lankford Virginia provides that no pension bounty disability or allowance save and except insurance benefits on which adequate premiums have been paid and hospitalization under existing law shall be paid or allowed to any veteran of any war for an injury or disease not of service origin except a veteran who is permanently and totally disabled or a veteran who has attained the age of 65 years and whose gross income is less than \$3000 The bill does not apply to dependents of deceased veterans

CORRECTION

Nomination of Surgeon General of Navy—THE JOURNAL of February 11 page 434 stated that Capt. Charles M Oman had been appointed surgeon general of the navy The Senate has not thus far confirmed the appointment and the indications are that his nomination will not be confirmed at the present session of Congress because the Senate is refusing to permit nominations of the outgoing administration to be acted on Capt John B Dennis a assistant chief of the bureau of medicine and surgery navy department is acting in certain matters while Secretary of the Navy Adams is performing official duties ordinarily performed by the surgeon general

Roentgen Rays in Diagnosis of Placenta Praevia

At the Edinburgh Obstetrical Society a new use was described for the roentgen rays—their assistance in the diagnosis of placenta praevia—by Prof Munro Kerr and Dr W G Mackay Introducing the subject, Kerr referred to the high percentage of maternal deaths in placenta praevia and the importance of adopting the method suitable to the individual case if this mortality was to be reduced There was difficulty not only in diagnosing the variety of placenta praevia present but also in differentiating between placenta praevia and accidental hemorrhage Therefore any method that would not only differentiate placenta praevia from accidental hemorrhage but also show which variety was present was valuable He then called on Dr Mackay to demonstrate a method which they had investigated together

Mackay first discussed previous investigations that had been made in order to locate the position of the placenta in the uterus The only one at all satisfactory was that of Manees, Miller and Holly, who injected strontium iodide into the amniotic sac The placenta, which projected into the cavity, produced a defect at the edge of the shadow when the uterus was pictured from the correct angle Kerr and Mackay tried this method in ten cases but gave it up, as the fetus died in three cases They substituted a derivative of iopax, which is nontoxic and nonirritant, for strontium iodide They found that 20 cc produced a suitable shadow In ten cases in which this procedure was followed, no untoward effects occurred to either the fetus or the mother, though the injection had a great tendency to terminate the pregnancy It was necessary to take at least two roentgenograms, one anteroposterior and the other lateral so as to be sure of getting a full view of the indentation made by the placenta A number of roentgenograms were thrown on the screen demonstrating the position of the placenta not only in normal cases but also in cases of placenta praevia In the latter they showed exactly how much of the placenta was in the lower segment and covered the os Various errors that had to be avoided, such as those due to gas in the bowel and to the presence of two sacs, were described It was also shown how roentgen rays could in certain cases enable the sex of the child to be diagnosed and show whether any coils of cord were round the child's neck

Sir Percy Sargent

The death at the age of 59 from pneumonia of Sir Percy Sargent has removed the leading neurologic surgeon in this country Educated at St Thomas's Hospital, he obtained in 1895 the usual junior surgical appointments and then came under the influence of Sir Charles Ballance and acquired his bent for neurologic surgery from him At this time Sir Victor Horsley the pioneer of neurologic surgery in England, was developing the surgery of the brain at the National Hospital (the center of British neurology) Sargent was appointed his assistant and turned his great manipulative skill to account in the delicate operations on the nervous system The speed and ease with which he performed difficult operations were a revelation He could deftly remove a tumor from the spinal cord in twenty minutes He was the pupil and direct successor of Horsley with whom he worked for eight years During the war he did great work in the treatment of injuries of the nervous system and as a result of this experience produced his monographs on Injuries of the Peripheral Nerves and the Spinal Cord which were published by the Medical Research

Council He was too busy in practice to write much, but what he wrote was always excellent His earliest important paper was written in conjunction with Professor Dudgeon on the Bacteriology of Peritonitis Others were "Peritonitis" and "Diseases of the Appendix" in Choyce's System of Surgery, "The Treatment of Penetrating Wounds of the Skull" (with Gordon Holmes) in the *British Journal of Surgery*, and "Closure of Cavities in Bone," in the *Journal of the Royal Army Medical Corps* Though he attained such eminence as a neurologic surgeon, he was essentially a general surgeon, and, not wishing to pose as a specialist, he avoided publishing the wealth of material in his special branch which he accumulated, but he had in preparation at the time of his death a book on neurologic surgery

The Falling Birth Rate

The registrar general's provisional vital statistics of England and Wales for 1932 have just been published For the fourth year in succession the birth rate is the lowest on record, being 1 per thousand below that of 1929 and 1930 and 0.5 below that of 1931 The death rate is 0.3 below that for 1931 The infant mortality rate is 1 per thousand below that for 1931 The only year showing a lower rate is 1930 In 1928 the rate was the same, namely, 65 The actual figures for 1932 are

	Rate per 1,000 Population	Deaths Under One Year per 1,000
	Live Births	Deaths (Crude Rate) Registered Live Births
London (Administrative County)	14.3	66
England and Wales	15.3	65
118 County Boroughs and great towns including London	15.4	68
126 smaller towns with estimated resi- dent populations of from 25,000 to 50,000 at 1931 Census	15.4	57

The Medical Profession and the Financial Depression

Physicians generally and specialists in particular are suffering from the most severe slump known to the medical profession It of course is the result of the unprecedented financial depression of the country, which forces even those who were rich to practice severe economy and in many cases avoid consulting physicians if possible Operations that are absolutely necessary are performed as heretofore, but those which are not are postponed until better times Many patients who in other days would have paid a surgeon's fee without demur and had operations performed in a nursing home now find this beyond their means and go to swell the crowds at the hospitals Another result is that in many cases fees have had to be reduced Those who suffer least are the panel physicians, whose income is guaranteed by the state It is true that they have suffered a small cut, but it is trivial compared to the losses of those who rely on private practice

The Influenza Epidemic

An epidemic of influenza is common at the beginning of the year One is now prevalent all over the country The disease is of mild type but is so general as to cause some interference with business So many nurses are suffering that the outpatient department of the North Staffordshire Infirmary has had to be closed In many parts of the country, schools are closed In Yorkshire villages the absence lists of children from school have reached 75 per cent At Swansea so many whole families are laid up that it has become a practice to give physicians the key of the house so that they can let themselves in The deaths from influenza registered in the 118 large cities in England and Wales for the week ended January 21 were 1,589, against 120, 303, 681 and 1,041 in the preceding four weeks As the last figure shows the disease

was prevalent in the last week of 1932 and then declined, to be followed by the present increase A general decline in the disease is soon to be expected if experience of earlier epidemics is a guide

Dr Malcolm Evan MacGregor

Dr Malcolm Evan MacGregor, who was in charge of the Wellcome Entomological Field Laboratories, has died at the age of 43 Educated at Trinity College, Cambridge, and later a Carnegie fellow at Harvard, he came under the influence of that great medical entomologist Dr L. O. Howard He was appointed university research student in medical entomology at Cambridge He came into prominence in the war, when in charge of the mobile field laboratories which investigated insect carriers of disease in East Africa He studied mosquitoes with a view to solving some of the fundamental problems underlying their mode of life, feeding, hibernation and reproduction He showed that the diverticulum of the esophagus is a reservoir into which the mosquito can direct fluids unsuitable for the stomach He studied the effect of ultraviolet rays on the larvae and the reactions of the waters in which they occurred and he endeavored to show that the larvae of *Culex* and *Anopheles* live in waters of different but particular pH His research was in full operation at the time of his death He wrote numerous scientific papers and a handbook for anti-malaria workers, entitled "Mosquito Surveys"

Charges of Fraud in Conduct of Examination for Internships

The alleged fraud connected with the competitive examination for internships continues to be the chief topic of medical discussion and to give rise to numerous articles by notable people in the daily press A thorough inquiry has revealed that of 800 examination papers which, according to the regulations, should have been anonymous, 232 bore marks evidently designed to identify the authors Only eighteen of the papers of the successful candidates bore such marks As regards the 214 others, the attempt to commit fraud brought no results Of the twelve interns mentioned who read to the judges the unsigned examination papers, two confessed having made some "ameliorations" in the text of certain of the candidates, but, they aver, only to correct mere slips of the pen, which would not have sufficed to make excellent papers out of those that were bad As already announced, one of these readers committed suicide It has been emphasized that in making a selection of the eighty candidates from among 800, the second half of the list contains candidates whose rank in scholarship is almost identical, and that makes it necessary to take into account minute details (half points and quarter points), in order to differentiate between them It is here that fraud may give an advantage to candidates who find accomplices among the readers of the examination papers At present, the director of the Assistance publique a Paris and the minister of public health, who have to assume the responsibility of deciding the matter, are hesitating between two solutions (1) the total annulment of the recent examination or (2) the rejection of the candidates whose papers bore identifying marks contrary to the regulations The 720 candidates who failed demand a second examination, whereas the eighty students who have been accepted do not wish to submit to a second examination It cannot be denied that chance plays a considerable part in competitive examinations One cannot determine the real worth of a man by the manner in which he treats a subject selected at random There are young persons who can write readily on any subject, and for them a competitive examination is an easy task There are

others, with less retentive memories, to whom an examination is repugnant, and yet later they might become just as efficient clinicians as the former

The Treatment of Experimental Syphilis

Some hope is based on apparatus using short hertzian waves to cure certain infectious diseases by raising the temperature of the body. The experiments with the gonococcus have given only mediocre results. In dementia paralytica and tabes, the results are not better than those secured by means of malaria therapy. Research of the same nature on experimental syphilis in the rabbit and then on syphilis in man was undertaken by Richet and Dublineau. They based the treatment on the extreme fragility of the spirochete toward heat, since a temperature of 41 C. for thirty minutes kills the spirochete, or at least suppresses its virulence. If the rectal temperature of the rabbit is raised to 42.4 C., for from seventeen to twenty-two minutes, syphilis will sometimes be cured, if at the same time one injects into it an infracurative dose of neoarsphenamine, one will always effect a cure (biologic recovery). The speakers referred to clinical results obtained by the use of combined chemotherapy and pyretotherapy. In thirty-eight patients a clinical cure was confirmed, and in thirty-five cases a Wassermann test was found to be negative.

Convalescent Serum in Prevention of Measles

Lereboullet and J. Vanier reported, before the Société de pédiatrie, a small outbreak of measles in a ward in the Hôpital des enfants-assistés. They announced the results of injections of the serum of measles convalescents in all the children who were infected as the result of three cases that developed in the department. The injection of serum of measles patients did not prevent measles from developing, but there was evidence of attenuation, nine of the children thus injected having presented a benign type of measles. The only child who was not injected developed a grave type of measles with bronchial pneumonia and otitis which ended, however, in recovery. When the outbreak of measles was over, the ward was reopened to patients who had not had measles serum injected. Three new cases developed at once, one of which proved fatal, while another was severe. From then on, serotherapy was applied to all the children admitted to the ward, and of forty-one entrants not one developed measles.

Protest Against Compulsory Notification of Tuberculosis

The bill filed by Justin Godard, former minister of health which would make the notification of tuberculosis compulsory for the physician, has raised the same protests that were always raised in the Academy of Medicine whenever this question was discussed. Mr. Auguste Lumière, who supports the thesis that tuberculosis is rarely contagious but is hereditary or inoculated by cow's milk, is the leader of this movement. In an article that has created considerable stir, he seeks to prove that the number of tuberculous persons is countless and that it would require an army of physicians and an enormous expenditure of money to detect them all. Even though that result were accomplished there is no feasible plan of isolating all tuberculous patients. They would refuse to be separated from their family. Although the number of beds reserved for tuberculous patients in the sanatoriums and the hospitals has been considerably increased it would be impossible to admit them all. Finally if the tuberculous person is prohibited from working the support of his family will necessitate the expenditure of enormous sums that the Budget of France is absolutely unable to furnish. Physicians would refuse to make a notification the consequences of which would bring a catastrophe to their clients. That is the opinion of the Fédération des syndicats médicaux de France, expressed on several occasions. The physician demands

that his initiative shall not be controlled by an absolute law but that he shall be allowed to judge of the cases in which the presence of a tuberculous person in his family constitutes a real danger for his entourage. Under these conditions, it would appear that Mr. Godard's bill is likely to encounter serious opposition in parliament.

Fee Splitting

In the *Deutsches Aerzteblatt*, the official organ of the Deutscher Aerztevereinsbund, the leading professional organization, the editor, Dr. Vollmann, presents the views on dichotomy that prevail in various countries. In France, vigorous protests against the practice are being raised, in Belgium, dichotomy is the accepted custom, although the demand is made that the patient be informed of the splitting of the fee, in many countries it is more or less an objectionable custom secretly practiced, the English medical profession rejects it in toto, and, in the United States, one medical organization demands of its members a written statement that they do not practice fee splitting. In Germany, the conceptions of the medical profession are absolutely opposed to a division of fees. It appears, however, that the increasing economic difficulties are causing some physicians to practice dichotomy secretly. This fact furnished the occasion for Dr. Vollmann's utterances, which expressed the strongest opposition to fee splitting. If the family physician of the patient, at his request, is present at the operation, he gives the patient service that entitles him to a fee. It does not seem likely that any patient will object to that. But the patient must have no reason to suspect that the advice to submit to an operation and the recommendation of a certain surgeon may have been inspired with thought of monetary gain. He continues, "We be it to the physicians if the patient cannot banish such suspicions, if he must fear that the advice to submit to an operation is influenced by subjective motives or by greed of gain. The family physician or the general practitioner, who advises the patient and whose duty it is, in case of need, to consider, together with a specialist, the possible indications for an operation, must be the loyal counselor of the patient, or, in other words, his confidential adviser." Vollmann thus expresses the view of the vast majority of German physicians, and they will be grateful to him for having made himself the exponent of their views while it is still a question of a few rare violations.

The Hygienic Evaluation of Water

At the Giessen session of the Deutsche hygienische Gesellschaft, in September, 1932, criteria regarding the hygienic evaluation of water, as formulated by Professor Kiskalt of Munich and Professor Heisser of Frankfurt-on-Main, were unanimously adopted. According to these criteria, the evaluation of water and of the sources of supply must consider first the purpose for which the water is to be used and not the method of production. Only the medical, hygienically trained expert is competent to determine the hygienic value of water, the entire bacteriologic examination must be left to him. The society uttered a warning, in the interest of public health, against allowing these extremely important duties to pass out of the hands of these specialists. It considers the demand that for the evaluation of drinking water only the quality of the product and not the origin of the water should be taken into account as entirely wrong. It adopted the point of view that the hygienic demand that all water for bathing purposes and especially drinking water shall possess in every respect an acceptable quality must be upheld. It is hardly likely to prove feasible, within the range of true economy to convert by purification processes waste water into drinking water that would

be constantly free from all substances dangerous to health and at the same time be of an agreeable quality. That would necessitate an extensive plant and equipment and such a large trained personnel that the economy effected in procuring the untreated water supply would be more than offset by the cost. Furthermore, so many analyses of the water by experts would have to be made that the cost of conversion would be greatly increased. The highest courts, moreover, have always taken the stand that a foodstuff is to be regarded as "spoiled" if it awakens disgust in the average person when he learns of the true mode of production. It is not necessary to show that it has undergone changes, but it is sufficient if the use of such water awakens disgust and therefore is contraindicated. Furthermore, the forced impairment, by means of so-called rational considerations, of the reactions of the general public to what is regarded as esthetically displeasing, appears to be of extremely doubtful expediency.

Hair Dyes in Relation to the Skin

In Germany, from 2,000,000 to 2,500,000 persons dye their hair regularly or have it dyed. Each of four or five of the larger firms that manufacture hair dyes have an annual output of from five to six million packages, and the smaller firms taken collectively put out about the same amount, so that the total amounts to about 35,000,000 packages. The physician must admit that, in spite of the enormous consumption, comparatively few cases of skin irritation come to his attention, as H. Meyer brings out in a recent number of the *Deutsche medizinische Wochenschrift*. Substances that are known to be harmful have been excluded by law in the process of manufacturing. In the ready-to-use hair dye there is usually an alcohol-containing solution, thickened by the addition of gums or soaps and made strongly alkaline with ammonia. The manufacturers have been compelled by public demand to shorten the time of action of hair dyes, and an increase in the genuineness of the dyes has been attained by making them more alkaline, since only the strongly alkaline dyes penetrate deeply enough the horny substance of the hair and oxidize rapidly. The alkaline content of the dye is commonly the irritating substance, whereas irritation resulting from the dye proper occurs only secondarily. The most aggressive alkaline substance employed is ammonia, but ammonia is also the only volatile alkaline substance, and hence is irreplaceable in the preparation of a hair dye of high quality.

National Congress of Surgery

The thirty-ninth Congresso nazionale di chirurgia was held recently in Rome, under the chairmanship of Prof. Roberto Alessandri, director of the Clinica chirurgica of the University of Rome.

ACUTE PERITONITIS

The speakers on the topic "Acute Peritonitis" were Prof. Baldo Rossi and R. Fumagalli of Milan for the surgical side, Dr. Mucchi of Milan for the radiologic part, and Prof. Dante Casella, head of the department of surgery of the Ospedale militare in Rome, for the military side. Owing to the death of Professor Rossi, the surgical side of the topic devolved entirely on Professor Fumagalli. He called particular attention to the excellent results that can now be obtained with a careful diagnosis and timely intervention.

Dr. Mucchi pointed out that it has been regarded as generally contraindicated to subject peritonitis patients to a radiologic examination. It was thought that the information thus obtained would not compensate for the danger and the inconvenience associated with the examination. Encouraged, however, by the conclusions of certain authors who had studied this subject (to mention Laurell and Westerborn), the speaker examined

roentgenologically a large percentage of the peritonitis patients admitted to the Clinica chirurgica in Milan, during the first six months of 1932 (about eighty patients). In addition to the fluoroscopic examination, roentgenograms of the abdomen were made. No contrast medium was used, nevertheless, the author obtained information that clarified the peritoneal process. The exudate may be visible, also its fluctuation, if it is abundant, or otherwise multiform roentgenographic images, the intestinal lumen was round instead of polyhedral as is observed in simple meteorism. Among the indirect signs were paralytic ileus, edematous infiltration of the abdominal walls, changes in the position and mobility of the diaphragm, and pleural inflammations. In perforate peritonitis, gas in the abdominal cavity was nearly always recognizable. With more experience, the speaker expects to extend the data thus far collected. His paper was illustrated with numerous paragraphs.

Professor Casella spoke on acute peritonitis in military hospitals. The perforation of a gastric or duodenal ulcer, he said, is sudden and constant in the peritoneal reaction, which may be confined to the site of the perforation. There are stabbing pain, shallow breathing and an immediate reaction of the rectus muscles, which produces a woody consistency, which is resistant even to general anesthesia. In the first stage one may observe, on percussion, a tympanic note in the upper part of the abdomen, whereas the liver dullness frequently disappears. Other symptoms may be vomiting, constipation, abnormal temperature and pulse, and, exceptionally, subcutaneous emphysema. In case of doubt as to the diagnosis, it is well to administer orally, before operating, a colored solution, as recommended by Gibson. The operation should be as early as possible, for a delay of a few hours may have serious consequences. Spinal anesthesia is preferred. The extent of the operation will vary with the circumstances. Careful cleansing of the abdomen is preferable to lavage. Recoveries in the military hospitals amounted to 55 per cent of the cases, but among those operated on early, 80 per cent of the patients recovered. In peritonitis due to perforation of a typhoid ulcer, the recoveries amounted to 33 per cent. In such cases, an immediate operation is indicated, irrespective of the general condition of the patient, but the prognosis is nevertheless always uncertain. The operator should traumatize the tissues as little as possible. Cleansing by dry methods is always useful. In 90 per cent of the cases the perforation occurs in the more distal 60 cm. of the small intestine, in 10 per cent the colon and the appendix are involved.

Acute peritonitis due to appendicitis, the most frequent form, causes little pain at the start. The Ospedale militare in Rome admitted, during the past five years, 227 patients with appendicitis, in 187 of whom there was acute peritonitis. In this series there were fourteen deaths and 173 recoveries, or 92.5 per cent. In all the cases of peritonitis an operation was performed, and when sure of the diagnosis, the Lennander-Jalaguer incision was always employed.

Traumatic peritonitis in the army is due chiefly to a fall, a kick by a horse or the passing of a wheel over the abdomen. The speaker favored prompt operation when the diagnosis is unquestionable. In other cases, he advises watchful waiting for a few hours. In patients operated on within a few hours of the accident the military hospitals record 31 per cent of recoveries. In the discussion of the papers Donati of Milan brought out that the operations vary if peritonitis is already established. In that case the condition of the patient may be aggravated by the operation. Donati stated that suture of the ulcers was not usually difficult during the first hours but might become difficult as time went on. He agreed that the radiologic examination is important. As to drainage, he thinks that the criterion of time is important and that it may be advisable to close the abdomen without drainage when the operation occurs during the first hours.

CHRONIC HEPATITIS

The second topic, "Chronic Hepatitis," was developed in collaboration with the Società di medicina interna. The surgical discussion was entrusted to Prof G Pascale and to Professor Chiariello of Naples. The speakers reviewed the methods that surgery offers for the functional exploration of the liver but concluded that few of them can be fully endorsed. Among these are the van den Bergh test and the determination of the bilirubin in the blood. From the surgical point of view, chronic hepatitis results chiefly from cholecystitis and from appendicitis and other gastro-intestinal conditions. The speakers reviewed these various forms and then considered the surgical possibilities in atrophy of the liver. Drainage of the biliary passages should always be done in these cases, it may serve to reveal an error in the diagnosis, and often cholecystotomy proves beneficial in cases of primary hepatitis. In about 50 per cent of the hundred cases in which an operation for acute yellow atrophy was performed, a recovery was effected by the intervention.

Referring to the surgery of hepatic cirrhosis, the speakers recalled the Italian contributions in this field. The Talma method, known also as the Morrison or the Drummond-Morrison operation, consists in the fixation of the omentum to the parietal peritoneum. In ascites due to hepatic cirrhosis, many interventions have been advised—which, however, may all be reduced to two types, one based on the principle of draining the fluid into other parts of the body, the other consisting in anastomosing the portal vein and the vena cava to reduce the flow of blood from the portal vein to the liver.

In the discussion, Prof Roberto Alessandri of Rome called attention to the need of distinguishing between the various forms of hepatitis. In some types, surgery is frankly indicated (occlusions due to neoplasms and gallstones, for example) while in other types the surgeon can aid only if summoned in time.

Professor Pende of Genoa said that research carried out in his institute revealed that the thymus exerts an inhibitive or regulatory action on the hepatic cell and that possibly the spleen has a similar action. The surgery of cirrhosis and of chronic hepatitis must continue to rely on the modern functional liver tests.

Pavia was chosen as the meeting place for the next congress. The topics on the program will be "Drainage of the Biliary Tracts" and "Diseases Due to Lesions of the Parathyroids," the latter being discussed in collaboration with the Società di medicina.

New Anatomy Building in Genoa

The Città degli studi in Genoa has recently acquired a new building called "il palazzo della anatomia." This is the eleventh large university building erected in Genoa in recent years. To complete the plans as originally adopted, the building for the surgical clinic and that for the obstetric clinic will soon follow. The "palazzo dell'anatomia" is U shaped and has a capacity of 29,000 cubic meters. It will house in addition to the institutes of normal and pathologic anatomy, the departments of legal medicine and of operative surgery, and the municipal morgue.

The Death of Augusto Murri

Prof Augusto Murri, the eminent clinician at the University of Bologna, has died at the age of 94. Sprung from a noble but poor family, Murri was able to pursue with difficulty a university course. On returning to Italy from abroad, he accepted a small post as health officer where he remained until Guido Baccelli, who had read an article written by him in Germany on acute yellow atrophy of the liver, chose him as his aid. He was given the chair of clinical medicine in Bologna in 1895. At that time he had already published an excellent

work on "The Regulatory Mechanism of Animal Temperature," and another on "The Theory of Fever." His scientific work culminated in his research on hemoglobinuria due to cold. It was Murri who established that, while Starling's "law" holds good for the healthy heart, it is not followed by the diseased heart, which acts, on the contrary, according to norms that Murri established and which many call "Murri's law." Murri was one of the first Italian neurologists. He did research on chronic hydrocephalus, polyclonia and chorea, and Addison's disease. Murri retired, on account of age, in 1926. He is the only Italian, besides Golgi, to be chosen an honorary member of the Berliner Medizinische Gesellschaft.

Reduced Iron in Treatment of Secondary Anemias

Drs J Barbosa Correa, Lauro Cruz and J B Monteiro de Barros Netto of São Paulo have published an interesting work on reduced iron in the treatment of secondary anemias. The studies of Starkenstein, Naegeli, Herz and Morawitz have shown that in anemia not all iron preparations are equally active and that iron is absorbed best in the form of ferrous chloride. Ferrous chloride is unstable and it is better to prescribe reduced iron, which is changed to ferrous chloride in the stomach. Naegeli has shown that the doses employed (from 0.1 to 0.3 Gm) are insufficient and that it is necessary to give 3 Gm daily and often more. He gives 3 Gm of reduced iron three times a day, twenty minutes before meals, in cases of achlorhydria or hypochlorhydria, he adds a little hydrochloric acid. The diet of the patient is not changed. The results obtained with this treatment are excellent even when other means have failed. Reduced iron taken on an empty stomach and in the indicated dosage is well tolerated.

Estimating the Amount of Hemoglobin

Drs O P Santos and E Moura Campos, of São Paulo, have estimated the hemoglobin of seventeen normal individuals by the method of van Slyke (capacity of the blood to fix oxygen) and by the method of Wong (dosage of iron). The hemoglobin values obtained by these two procedures differ greatly. This is surprising at first when one thinks that hemoglobin fixes oxygen proportionately to its iron content. But, as demonstrated by the authors, other factors influence the fixation of oxygen such as temperature and especially the pH of the blood and the alkali reserve. When the partial pressure of carbon dioxide increases, the pH rises and the fixation of oxygen is inhibited, in the case of acidosis, the results obtained by the method of van Slyke are naturally lower than those given by the dosage of iron. The differences found may, however, be explained by the influence of the blood carbon dioxide on the phenomenon of oxidation.

Introduction to Study of Neuropsychic Development of Nurslings

Dr Hosannah de Oliveira, who is a teacher of clinical medicine in the Faculty of Medicine of Bahia, says that the neuropsychic development of nurslings has never been given the place it deserves in the study of disturbances of nutrition and of diseases. To understand the mental and nervous pathologic conditions of infants it is necessary to know the development of their mentality during infancy. In the new-born, the weight of the brain is relatively larger than in the adult: it is equal to one sixth or one eighth of the weight of the body instead of to one thirtieth or one thirty-fifth of the weight as found in adults. The parts of the cerebrospinal axis do not all develop simultaneously: the pyramidal path is completed only at the age of from 2 to 3 years. Virchow has said that the nursing is

a "spinal being" not dominated by the brain. The higher centers develop later, little by little, the reflexes are modified, Babinski's sign disappears, and the brain predominates over the spinal cord. Many causes retard this evolution, such as hereditary and constitutional factors, obstetric traumatism, congenital debility, precocity, disturbances of nutrition, parental infections and intoxications (syphilis, alcoholism). Abnormal infants may be classified in three groups: retarded, imbecile and idiots. The psychology of the nursing permits observations that would be impossible later on. Its psychic development occurs in successive steps, which are usually characterized as the intuitive period, the expressive period and the impulsive affective period. These stages, according to age (Sante de Sanctis), are, first, from 0 to 3 years, second, from 4 to 6 years, third, from 7 to 12 years. Then follows adolescence, from 13 to 20 years.

The Chair of Pharmacology of Rosario

The Academic Council of the Faculty of Medicine of Rosario, at the termination of the three year contract of Prof. Enrique Hug, offered to fill the chair of pharmacology on a competitive basis. Drs. Hug and S. M. Neuschlosz took part in the competition. Dr. Hug is Argentinian. The other candidate had the support of various professors of Rosario, who claimed that there was no reason to go to Buenos Aires for a professor. Neuschlosz collaborated on the "Handbuch der normalen und pathologischen Physiologie," and he had worked in Germany. The reports made relative to the qualifications of the two candidates inflamed local feeling in Rosario with the result that, at the election by the council of professors, Neuschlosz obtained thirty-three votes while Hug obtained only nineteen. This vote has provoked protests and indignation in all the scientific circles of the country.

Murmurs Observed in Cases of Myocardial Infarct

In this country, the study of coronary occlusion has been the subject of many publications. At the Academy of Medicine, Oct. 23, 1931, Prof. M. R. Castej described a sign which he observed in five cases (*Prensa med. argent.*, 1932, No. 19). It consists in the appearance of a murmur occurring in the middle and toward the end of the systole and is soft and not influenced by position of apnea. It predominates in the region of the apex or above it when the infarct occurs at the base (mesotelesystolic murmur) or at the apex when the infarct is apical (protosystolic murmur). In some cases it persists but in others it may disappear with the evolution of the disease. The murmur is not found in all cases of myocardial infarct.

National Scientific Awards

The annual awards of the national government for the best scientific works have been made for 1929 and they have been given for medical work. The first award, of 30,000 pesos, has been conferred on Prof. M. R. Castej for his work "Arterial Hypertension," the second one has not been given and the third, of 10,000 pesos, went to Dr. M. Royer for his book "Uroblin in Normal and Pathologic Conditions."

Outbreak of Bacillary Dysentery

Although there was a small epidemic in Catamarca, cases of bacillary dysentery have been rarely described in this country. Recently there has been an epidemic of dysentery among adults and children, with five deaths, in the village of Las Varillas, province of Cordoba. Investigations made by Sordelli and Savio demonstrated the presence of the Shiga bacillus, which was proved by cultures and agglutination tests. Summer diarrheas are well known in the country but bacteriologic studies

to find the bacillus of dysentery are rarely made. It is possible that bacillary dysentery is rather frequent in Argentina.

News

Dr. J. M. Obarrio has been nominated director of public assistance and sanitary administration of the city of Buenos Aires. From now on, the periodical *Prensa medica argentina* will appear every week and not every fortnight, as heretofore.

Congress of Surgery in Argentina

The fourth Congress of Surgery opened, October 9, in the medical school of Buenos Aires. During the mornings there were surgical clinics and in the afternoons discussions of the following topics: complications of surgery of the biliary tract, by Drs. E. Romagosa, J. M. Allende and A. Altube; treatment of fractures of the femoral diaphysis, by Drs. E. Finochietto, R. Finochietto and M. Gamboa; treatment of infections of the hand, by Drs. A. Baraldi and B. M. Galcagno. Drs. A. Gutierrez and A. Ceballos lectured on peridural anesthesia and abscess of the lung. Several surgical films were exhibited, there was an exhibit of surgical apparatus and materials. The fifth Congress of Surgery will be presided over by Dr. L. Finochietto, and the topics to be discussed will be acute intestinal obstruction in adults, and the treatment of fractures of the elbow.

Prizes from the Universities

The prizes given by the universities of Argentina for the best thesis in medicine for the year 1931 were awarded to Dr. E. A. Aubrun, for his thesis on pruritus and hyperesthesia caused by partial denervation, to Dr. V. G. Foglia, for his thesis on pancreatic regulation of glycemia, and to Dr. D. Provenzano, for his thesis on anesthesia and alkali reserve. The prize of dentistry was given to Dr. J. M. Fiorini for his thesis on phonetic education of patients with palatine fissures. The E. Wilde prize was given to Miss Telma Recca for a thesis on juvenile delinquency in the United States and in Argentina.

JAPAN

Dec. 15, 1932

Amendments to the Medical Laws

The home office is going to submit a new bill amending the laws for physicians and dentists. The draft, which was sent to the Central Sanitary Association for consideration, has been approved. It was said that the home office would establish the system of state examinations to license practitioners to practice in certain circles and places. But strong opposition compelled the office to withdraw these two restrictions. The home office intends to control the medical colleges which heretofore have been solely under the control of the education office. The education office is expected to oppose this new proposal.

Among other important items to be amended are the control of what is called "the pay clinic," the prosecution of unlicensed practitioners and the abolition of exaggerated advertisements. The pay clinic is to be required to use record cards with detailed information about the patient. The local government may see these cards at any time, if necessary for the administration of the clinic. The advertisements of medical men will be restricted to their titles and specialties. Their skill, methods of treatment, and their positions will not be allowed in the advertisements. If an unlicensed practitioner examines a patient, he will be sentenced to penal servitude for a maximum of six months or be fined 500 yen. If he assumes to be a licensed physician, he may be given one year in jail or be fined 1,000 yen. Physicians are to be required to keep professional secrets more strictly. If government officials who go to examine the clinic cards of the pay clinic reveal the secrets of physicians or patients, they shall be sentenced to penal servitude for six months or be fined 100 yen.

As for the medical men employed in a hospital of the "health union"—the hospitals under the management of those who are nonprofessional—the new law decidedly declares that those medical men shall belong to the local medical society that is a branch of the Japan Medical Association. This requirement will settle the disputes which now trouble those employed physicians and the association. They will be controlled by the association the same as its regular members.

Opening of St. Luke's Hospital

The opening of St. Luke's International Medical Center in Tokyo will be held, May 27, 1933. The money to construct this new institute was raised largely by popular subscription in the United States, soon after the great earthquake in 1923. It is the only American hospital in Japan and it has the only college of nursing in the entire Orient. It gives treatment to more than 300,000 outpatients and 7,000 inpatients annually. Invitations to the opening ceremonies were sent by Dr. R. B. Teusler, head of the Medical Center, and by Prince Tokugawa, president of the American-Japan Society in Tokyo. An American party headed by George W. Wickersham, the president of the Japan Society in America, is expected to be present. The celebration is of nation-wide interest, because the Japanese, especially those who suffered in that great earthquake, could never forget the gift of this hospital as a token of America's sympathy and kindness.

Special Examinations for Some Undergraduates

Private medical colleges have been accused by the public of being too lenient with their students. The educational department has announced that it will examine the undergraduates of the private medical colleges in order to enforce discipline. The examination will be on some clinical subject, which has not yet been made public. The subjects will be changed every year.

New Leprosy Sanatorium in Chosen

Since the antileprosy campaign in Japan proper has been most successful during the last year, the same methods will be tried in Chosen (Korea) in 1933. A new association for antileprosy work has just been established in Chosen and it will in the near future build a sanatorium of 2,000 beds. This sanatorium will be presented to the Chosen government, which will have charge of it under the control of the governor-general.

Koch Memorial Lectures

The late Baron Dr. Kitasato established a memorial lecture to commemorate the birthday of Koch. The nineteenth lecture was held December 11 at Keio University. Dr. Iyehara lectured before a large audience on the sanitary conditions in Manchuria and Dr. Sakurai on the action and application of radiation.

Marriages

JAMES WATSON KENNEDY Rochester Minn. to Dr. LILIAN M. LITCHER of Detroit Lakes recently.

BENJAMIN FRANKLIN JONES Atlanta Ga. to Miss Mary Elizabeth Waith of New York Dec. 22, 1932.

JAMES CHARLES KLEIN Hoboken N. J. to Miss Marie Annieri of Teaneck January 7.

ROBERT GOODMAN Powers Lake N. D. to Miss Alice Hendrickson of Fargo recently.

JOHN R. OSHEA Fargo N. D. to Miss Hazel Papermaster of Grand Forks recently.

GEORGE T. KAMIT Newark N. J. to Miss Rosalind Turk of Brooklyn Dec. 4, 1932.

NATHAN GOLDIE to Miss Shirley Beatrice Rozman both of Milwaukee January 1.

Deaths

Charles Spencer Williamson ♂ Chicago, Medical College of Ohio, Cincinnati, 1896, since 1912 professor of medicine and head of the department, University of Illinois College of Medicine, adjunct professor of medicine, 1901-1903, and professor of clinical medicine, 1903-1912, formerly assistant professor of diseases of the stomach and professor, Chicago Polyclinic, member of the Association of American Physicians and the American Society for Clinical Investigation, served during the World War as a lieutenant colonel in the U. S. Army Medical Corps, director of the School of Military Hygiene and Sanitation at Fort Oglethorpe, in 1917 was awarded the Certificate of Merit by the American Medical Association for an exhibit of research work, for many years on the staffs of the Cook County and the Research and Educational hospitals, editor of "French's Practice of Medicine" in 1910, aged 60, died, February 15, of coronary thrombosis.

Alfred Stephen Burdick ♂ North Chicago, Ill., Rush Medical College, Chicago, 1891, since 1921 president and general manager of the Abbott Laboratories, vice president and assistant general manager, 1916-1921, associate professor of medicine, Illinois Medical College, 1899-1904, president of the American Drug Manufacturers Association, 1923-1925, during the World War served on selective service board, number 59, in 1923 was appointed lieutenant colonel, medical reserve corps, author of "Standard Medical Manual," "The Remedy" and "Common Emergencies", aged 65, died, February 11, in the Highland Park (Ill.) Hospital, of pneumonia.

Lawrie Byron Morrison ♂ Brookline, Mass., University of Vermont College of Medicine, Burlington, 1902, member of the American Gastro-Enterological Association, American Roentgen Ray Society and the Radiological Society of North America, member and past president of the New England Roentgen Ray Society, on the staffs of the Huntington Memorial Hospital, New England Deaconess Hospital, Faulkner Hospital and the New England Baptist Hospital, Boston, aged 57, died, January 16, of carcinomatosis.

Parker Syms, New York, Medical Department of the University of the City of New York, 1882, member of the Medical Society of the State of New York, fellow of the American College of Surgeons on the staffs of the Midtown Hospital, New York City Hospital, West Side Hospital and the Lebanon Hospital, New York N. Y. Hospital and the All Souls Hospital, Morristown, N. J., aged 72, died, January 26, in Fitzwilliam, N. H., of cerebral hemorrhage, chronic valvular heart disease and nephritis.

Harry O. Sappington, Galveston, Texas, University of Texas School of Medicine, Galveston, 1898, member of the State Medical Association of Texas, at one time demonstrator of gynecology and obstetrics at his alma mater, formerly state health officer, city health officer and mayor, at one time superintendent of the John Sealy Hospital, in 1929 was placed in charge of the outpatient department of the U. S. Public Health Service, aged 72, died, January 27, of cerebral hemorrhage.

Robert Fitzsimmons Trainer, Williamsport, Pa., University of Pennsylvania School of Medicine, Philadelphia, 1898, member of the Medical Society of the State of Pennsylvania, at one time secretary of the Lycoming County Medical Society, served during the World War, city health officer, formerly county coroner, member of the board of education and inspector of schools on the staff of the Williamsport Hospital, aged 61, died, January 7.

George Howard Monks ♂ Boston, Harvard University Medical School, Boston, 1880, member of the American Surgical Association and the New England Surgical Society, fellow of the American College of Surgeons, at one time professor of oral surgery at his alma mater, formerly consulting surgeon to the Boston City Hospital, aged 79, died, January 26, of coronary disease and angina pectoris.

Edward Vincent Hogan, Halifax, N. S., Canada, McGill University Faculty of Medicine, Montreal, Que., 1896, professor of surgery and clinical surgery, Dalhousie University Faculty of Medicine, fellow of the American College of Surgeons, surgeon to the Victoria General Hospital and surgeon in chief to the Camp Hill Military Hospital, aged 59, died, January 20, of heart disease.

Raymond Clyde Wolfe ♂ Major U. S. Army, retired, St. Paul, Indiana University School of Medicine, Indianapolis, 1911, served during the World War, entered the medical corps of the U. S. Army as a first lieutenant in 1920 and retired with

rank of major in 1930 for disability in line of duty, aged 44, died, January 21, of aortitis and chronic nephritis

Jacob Wilford Wine ☉ Chicago, Chicago Homeopathic Medical College, 1895, Rush Medical College, Chicago, 1901, served during the World War, diagnostician in the contagious diseases department, Chicago Board of Health, on the staff of the Columbus Memorial Hospital, aged 65, died, February 3, of coronary thrombosis

Edwin Graffam Earle ☉ Chicago, College of Physicians and Surgeons, Chicago, 1891, formerly professor of histology and associate professor of medicine at his alma mater, on the staff of the Illinois Masonic Hospital and attending physician to the Columbus Hospital, aged 66, died suddenly, February 2, of angina pectoris

Frederick S. Luhmann ☉ Manitowoc, Wis., Rush Medical College, Chicago, 1877, Ludwig-Maximilians-Universität Medizinische Fakultät, München, Bavaria, Germany, 1880, at one time county coroner and member of the school board, formerly on the staff of the Holy Family Hospital, aged 80, died, January 10

Max Ernest Witte, Sr. ☉ Clarinda, Iowa, State University of Iowa College of Medicine, Iowa City, 1881, past president of the Iowa State Medical Society, member of the American Psychiatric Association, superintendent of the Clarinda State Hospital, aged 73, died, January 29, of cerebral thrombosis

Freeman Valentine Walker ☉ Captain, U S Army, retired, Bluffton, S C University of Virginia Department of Medicine, Charlottesville 1881, entered the army as an assistant surgeon in 1886 and was retired in 1906 under a special act of Congress, aged 72 died January 21, of angina pectoris

Naman Henry Soble, Elmira, N Y, College of Physicians and Surgeons in the City of New York, Medical Department of Columbia College, New York, 1890, member of the Medical Society of the State of New York, on the staff of St Joseph's Hospital, aged 69, died, January 16, of heart disease

Frank Ross Sherard ☉ Mobile, Ala., University of Pennsylvania School of Medicine, Philadelphia, 1894, fellow of the American College of Surgeons, on the staffs of the Mobile City Hospital and the Providence Infirmary, aged 60, died, Dec 30, 1932, of carcinoma of the stomach

Thomas C. Cochran, Kokomo, Ind., University of Louisville (Ky.) School of Medicine, 1891, member of the Indiana State Medical Association, city health officer, formerly county coroner, aged 69, died, January 28, in the Howard County Hospital, of carcinoma of the stomach

David Thomas Tayloe, Washington, N C, Bellevue Hospital Medical College, New York, 1885, member of the Medical Society of the State of North Carolina, fellow of the American College of Surgeons, proprietor of a hospital bearing his name, aged 68, died, January 10

John Z. Mraz ☉ Oklahoma City, Rush Medical College, Chicago, 1903, member of the American Urological Association, served during the World War, aged 50, on the staff of the Wesley Hospital, where he died, January 12, of tuberculosis, enteritis and peritonitis

Arthur Jordan, Helena, Mont., State University of Iowa College of Medicine, Iowa City, 1895, member of the Medical Association of Montana, city and county health officer, aged 63, died, January 13, in St John's Hospital, of heart disease and cerebral hemorrhage

John Harris Henson ☉ Mound Valley, Kan., Kansas City College of Medicine and Surgery, 1916, past president of the Labetti County Medical Society, member of the state board of health, aged 66, died, Dec 25, 1932, of bronchopneumonia and influenza

Albert James Brainard, Dayton, Ohio, Cleveland Homeopathic Medical College 1899, served during the World War, aged 56, for ten years assistant surgeon at the Veterans' Administration Home, where he died, February 1 of heart disease

George Elisha May ☉ Newton, Mass., Boston University School of Medicine, 1890, fellow of the American College of Surgeons, aged 72, died in January at the New York Post-Graduate Medical School and Hospital, of bronchopneumonia

Henry Bayard Whitehorne ☉ Caldwell, N J, Albany (N Y) Medical College, 1873, formerly secretary of the board of health of Verona and member of the board of education, aged 86, died, Dec 23, 1932, of cerebral hemorrhage

William Charles Jones, Hollister, Calif., University of Michigan Homeopathic Medical School, Ann Arbor, Mich., 1882, veteran of the Spanish-American War, aged 71, died, Dec 10, 1932, of bronchopneumonia and arteriosclerosis

Charles Hyde Davidson ☉ Lexington, Va., University of Virginia Department of Medicine, Charlottesville, 1894, county

health officer, on the staff of the Stonewall Jackson Memorial Hospital, aged 60, died, January 23, of pneumonia

Horace James Sims, Daphne, Ala., University of Tennessee Medical Department, Nashville, 1906, member of the Medical Association of the State of Alabama aged 61, died, Dec 10, 1932, of myocarditis and acute nephritis

Louis Warren Fargo, Augusta, Ga., University of Georgia Medical Department, Augusta, 1878, formerly instructor and assistant in pathology, secretary of the faculty and photographer at his alma mater, aged 80, died, Dec 14, 1932

Samuel Hirsh Segool ☉ Boston, Harvard University Medical School, Boston, 1928, aged 29, on the staff of the Boston City Hospital, where he died January 11, of thrombosis of the splenic vein and pulmonary infarction

William Johnson Clarke, Milford, Mass., Harvard University Medical School, Boston, 1867, Civil War veteran, for many years on the staff of the Milford Hospital, aged 89, died, January 17, of cerebral hemorrhage

Burton Adelburt Washburn, Paducah, Ky., Beaumont Hospital Medical College, St Louis, 1900, member of the Kentucky State Medical Association, served during the World War, aged 56, died, Dec 13, 1932

John Redmond Macnamara, Chicago, College of Physicians and Surgeons, Chicago, 1887, veteran of the Spanish-American and World wars aged 67, died, January 8, of carcinoma of the gallbladder and liver

George Samuel Morrow, Dayton Pa., College of Physicians and Surgeons, Keokuk, Iowa, 1887, member of the Medical Society of the State of Pennsylvania, aged 68, died, Nov 22, 1932, of cerebral hemorrhage

Ernest D. Mabry, Oklahoma City, Missouri Medical College, St Louis, 1895, member of the Oklahoma State Medical Association, aged 58, died January 12, in the Polyclinic Hospital, of carcinoma of the hand

H. Watson Moffitt, Washington, D C, Baltimore Medical College 1907, member of the Medical Society of the District of Columbia served during the World War, aged 48, died, January 22, of heart disease

Guy William Taylor, El Reno Okla. Memphis (Tenn.) Hospital Medical College, 1887, member of the Oklahoma State Medical Association, aged 72, died, Dec 18, 1932, of influenza and myocarditis

Thomas Claudius Bradwell, Waxhaw, N C, Medical College of the State of South Carolina, Charleston, 1912, aged 45, died, January 20, in the Baker Sanatorium, Charleston, of gangrene of the lung

William C. McCandless, Butler, Pa. Jefferson Medical College of Philadelphia, 1881, aged 75, died, in January, at the Butler County Memorial Hospital, of injuries received in an automobile accident

George Elwood Pumphrey, Carthage, Ill. Keokuk (Iowa) Medical College, 1897, member of the Illinois State Medical Society, served during the World War, aged 66, died, January 1, of pneumonia

Rollin Ledru Banta, Burt, N Y, University of Buffalo School of Medicine, 1871, member of the Medical Society of the State of New York, aged 86, died, January 13, in Newfane, of myocarditis

George Lewis Mack, Bound Brook, N J, College of Physicians and Surgeons, Baltimore, 1907, member of the Medical Society of New Jersey, aged 51, died, January 16, of heart disease

William H. Harrison, Loudon, Tenn., Vanderbilt University School of Medicine, Nashville, 1883, member of the Tennessee State Medical Association, aged 78, died suddenly, Dec 22, 1932

James Everette Coleman, Chicago, Loyola University School of Medicine, Chicago, 1928, aged 33, died, Nov 18, 1932, in the Provident Hospital, of cocaine poisoning, self-administered

Julius Johnston Grosvenor, Richmond, Ind., Indiana University School of Medicine, Indianapolis, 1911 served during the World War, aged 43, died, January 8, of influenza and encephalitis

Otto M. Kuehn, Waterloo, Ill., Ludwig-Maximilians-Universität Medizinische Fakultät München Bavaria, Germany, 1864 Civil War veteran, aged 90, died, January 5, of bronchopneumonia

Lee Ricard Martin ☉ Washington, D C George Washington University School of Medicine, Washington 1926 aged 32, was found dead, January 31, of poison, self-administered

H Rufus Boitnott, Dawson Springs, Ky, Hospital College of Medicine, Louisville, 1906, aged 56, died, January 29, in the Jennie Stuart Memorial Hospital, Hopkinsville, of septicemia

John Bell Dykes, Mankato, Kan, University of Tennessee Medical Department, Nashville, 1887, member of the Kansas Medical Society, aged 72, died, Dec. 26, 1932, in Washington, D C

Dallas Dee Davis, Onawa, Iowa, University of Nebraska College of Medicine, Omaha, 1925, aged 32, died, January 19, as the result of an electric shock from a roentgen-ray machine.

Carlos Manuel Riveroll, Los Angeles, Universidad Nacional Facultad de Medicina, Mexico, D F, 1907, aged 54, died, Dec. 1, 1932, of pulmonary edema and bronchopneumonia

Jay Dever Linton, Philadelphia, Jefferson Medical College of Philadelphia, 1902, served during the World War, aged 54, died, January 17, in the U S Naval Hospital, of pneumonia

Mary Adelaide Stolz, Berkeley, Calif, New York Medical College and Hospital for Women, 1897, aged 79, died, Dec. 6, 1932, of auricular fibrillation and arteriosclerosis

Richard Huckstep Holt, Middleburg, Va, University of Virginia Department of Medicine, Charlottesville, 1925, aged 34, died, January 2, of carbon monoxide poisoning

Christian M Fager, Harrisburg, Pa., University of Pennsylvania School of Medicine, Philadelphia, 1881, aged 72, died, January 22, of coronary thrombosis and angina pectoris

James Douglas Ward, San Antonio, Texas (licensed, Texas, year unknown), veteran of the Spanish-American War, aged 71, died, January 13, of cerebral hemorrhage

Gerard Charles Mangini, Waterbury, Conn, Regia Università di Napoli, Facoltà di Medicina e Chirurgia, Italy, 1907, aged 51, died, January 10, of pneumonia

Walter FitzGerald, New York, Harvard University Medical School, Boston, 1930, on the staff of the Bellevue Hospital, aged 28, died, in January, of pneumonia

Byron Stager Turner, Chicago, Chicago Medical College, 1887, aged 69, died, January 7, of thrombosis, cerebral hemorrhage and carbuncle of the neck

Henry Horace Rogers, Los Angeles, Kentucky School of Medicine, Louisville, 1882, aged 77, died, Dec. 25, 1932, of chronic myocarditis and nephritis

William Polk Moore, Jr, Portland, Tenn, Vanderbilt University School of Medicine, Nashville, 1882, aged 75, died, Dec. 23, 1932, of chronic cystitis

George M Mockbee, Hillsboro, Mo, American Medical College, St Louis, 1882, formerly county coroner, aged 74, died, January 2, of heart disease

Frank Joseph Marecic, Flatonia, Texas, Kansas City College of Medicine and Surgery, 1919, aged 42, died, Dec. 15, 1932, of a streptococcal infection

Charles T Lancaster, Sadieville, Ky, Cincinnati College of Medicine and Surgery, 1889, aged 69, died, January 8, of cerebral hemorrhage

Joseph P Riddle, Rushville, Ohio, Medical College of Ohio Cincinnati, 1885, aged 73, died, January 26, in the Mercy Hospital, Columbus

Vincent Rockwell Killen, Long Beach, Calif, Rush Medical College Chicago 1900, aged 56, died, Dec. 4, 1932, of coronary occlusion

Samuel Hampton Halley, Lexington, Ky, Hospital College of Medicine, Louisville, 1898, aged 61, died, January 19, of heart disease

Francis Ferdinand Lang, Hettinger, N D, Bennett Medical College Chicago 1912, aged 47, died suddenly, January 13, of heart disease

Albert Minear Fulton, Thomas, Okla, College of Physicians and Surgeons Chicago, 1893, aged 64, died, Nov. 3, 1932, of pneumonia

Nelson Tatum Rice, Blaine, Ky, Louisville Medical College 1886, Civil War veteran, aged 80, died, Dec. 24, 1932, of pneumonia

Eugene John Wislocki, San Jose, Calif, University of Cracow Poland 1887, aged 71, died, January 9, of heart disease

Frank D Fanning Butler, Ind, College of Physicians and Surgeons Chicago 1897, aged 59, died, January 16, of pneumonia

Jesse Bowers McAfee, Dalton, Ga, Atlanta School of Medicine 1912, aged 47, died, January 17, of pneumonia

J M Gregory, Macon, Ga, Atlanta Medical College 1893, aged 70, died, January 9, of coronary thrombosis

Bureau of Investigation

WILLIAM HOWARD HAY Capitalizing Food Fads and Fantasies

During the past few years the Bureau of Investigation has received a large number of inquiries regarding Dr William Howard Hay, recently of East Aurora, N Y, but now at Mount Pocono, Pa. A physician in Washington, D C, wrote

I am enclosing herewith literature received by a patient of mine from Pocono Hay ven at Mount Pocono Pa. I understand that Dr William Howard Hay, the medical director, was for a long time the medical director of the Sun Diet Sanatorium at East Aurora N Y. I have heard a material amount of criticism, apparently well founded about the methods of the Sun Diet Sanatorium at East Aurora. Does the Association have any information of value concerning the institution?"

An Ohio physician inquired

Within the last few weeks I have had so many queries concerning Dr Hay's Sun Diet that I have been attempting to find some literature on the subject. They say that he has a sanatorium in East Aurora just outside of Buffalo and a more recent location in the Pocono Mountains called the Hay ven. His theory is that certain food groups do not combine well in the stomach and he has a chart showing the incompatibles which are groups that are usually combined for example meat and potatoes. Do you know anything about him and his diet as recommended for various diseases?"

From Boston this inquiry came, also from a physician

Can you give me any information on Dr Hay and the Hay diet which has become so popular in certain sections of our country? I believe that it is based on the idea of not eating meats and starches in the same meal.

These are but three of the most recent inquiries from hundreds that have come in within the past year or two

William Howard Hay, according to our records, was born in 1866 and holds a diploma from the Medical Department of the University of the City of New York, 1891. He was licensed in Pennsylvania the same year and, by endorsement, in New York in 1920. Dr Hay for a time was a member of his local medical society, but in 1930 his local society informed the American Medical Association that Dr Hay had resigned just before charges of unethical advertising were to be preferred against him. He seems to have practiced in Youngsville, New Castle and Corry, Pa, and he has claimed that for a few years he was the surgeon for the American Tinsplate Company of New Castle, Pa. He went to Buffalo, N Y, about 1921. In Pennsylvania he seems to have operated what was known as the Hay Rest Cure, for a clipping from a newspaper published in 1918 in Corry, Pa, recorded that Dr Hay had introduced 'a special service department for the cure of hay fever cases'

The American Medical Liberty League, which, as our readers know, is an organization devoted to the blackguarding of the American Medical Association in particular and of scientific medicine in general, sells a number of leaflet reprints. One of these is an article by William Howard Hay entitled "Who Are the Quacks?" in which Dr Hay develops the thesis that the quacks are not the food faddists, the cultists, the "drugless healers" the chiropractors, the naturopaths or the seventh-sons-of-seventh sons but are the members of the regular medical profession

Dr Hay appears to have been active some years ago in the American Association for Medico-Physical Research, another of the 'twilight-zone' organizations. This concern was dealt with at some length by the Bureau of Investigation in an article published in THE JOURNAL of Sept. 19, 1925. Dr Hay was also prominent in the so-called Defensive Diet League of America being a member of its Medical Advisory Board. The Bureau of Investigation published an article on that concern in THE JOURNAL of June 20, 1925. More recently Dr Hay seems to have joined that group of faddists who obtain publicity by disseminating propaganda against the use of aluminum cooking utensils

SUN AND DIET SANATORIUM

Dr Hay seems to have gone into what the showmen call 'big time stuff' when he became medical director of the East Aurora Sun and Diet Sanatorium which is operated from East

Aurora, N Y, a suburb of Buffalo This sanatorium was incorporated in 1927 under New York laws and is said to have taken over the assets and business of what had previously been known as the Sun-Cure Sanatorium, also a New York corporation The officers of the East Aurora Sun and Diet Sanatorium were said to be Oliver Cabana, Jr, president, Thomas Healy, vice-president, Fred D Morgan, secretary and managing director, and Clara B McCollum, treasurer Mr Cabana seems to be the chief owner of the Sun and Diet Sanatorium, although apparently his main business is that of president and treasurer of the Liquid Veneer Corporation of Buffalo He is also said to be connected with one of the Buffalo banks The files of the Bureau of Investigation contain some advertising matter put out some ten years ago by the Kemozone Laboratories, Inc, of Buffalo, N Y Kem-O-Zone was described as "The Aristocrat of Antiseptics" According to the letterhead at the time, the president and treasurer of Kemozone Laboratories, Inc, was Oliver Cabana, Jr Mr Thomas Healy, vice-president of the Sun-Diet Sanatorium, and Mr Morgan and Clara B McCollum, secretary and treasurer, respectively, of the Sanatorium, are all said to be connected with the Liquid Veneer Corporation

We learn from a circular of the Sun-Diet Health Service, which is affiliated, apparently, with the "sanatorium," that Mr Cabana in 1927 organized the East Aurora Sun and Diet Sanatorium as an institution that was to be "devoted to the removal of the cause of disease through the natural means of proper food and regulated exposure to the sun" The same circular records that Mr Cabana picked out for the medical

weeks, had been named defendant in the Federal civil court at Scranton in an action that was filed by the Sun-Diet Sanatorium, Inc, of East Aurora, N Y It went on to state that, in the first suit started two weeks previously by the Sun-Diet Health Service, Dr Hay was charged with breaking his contract and an injunction had been asked against his activities at Mount Pocono The later suit against Dr Hay and eight co-defendants asked \$200,000 and sought to restrain them from using the methods of the East Aurora concern The other defendants named in the newspaper report with Dr Hay were Carl J Gifford, Austin E Stutzman, Marie Thomas Best, Olive J Godfrey, Murdock D MacIver, Vivian Healy, Agnes Diamond and Agnes Beumer One may be excused for wondering if "one of nature's noblemen" is endeavoring to make it rather warm for Dr Hay

At this point, before leaving the East Aurora concern, it is of interest to the medical profession to know that Mr Cabana's new medical director, successor to William Howard Hay, is Rasmus Larrsen Alsaker Those of our readers with long memories may remember that the Bureau of Investigation published in THE JOURNAL of Dec. 10, 1921, an article entitled "The Alsaker Way" Dr Alsaker was born in 1883 and received a diploma from Bennett Medical College in 1910 Dr Alsaker has been an advertiser in a large way, issuing a series of "Books That Teach The Alsaker Way to Health and Efficiency" In some of the Alsaker advertising published when the doctor had been out of medical college barely seven years, he was heralded as an "eminent authority" who had "put the net result of his many years of professional experience with sick

people into his writings"! During one of the influenza epidemics, public fear was capitalized in an attempt to sell a book, "The Alsaker Way to Prevent and Cure Influenza, Catarrh, Pneumonia and Other Troubles of the Nose, Throat, Lungs, Etc"

HEALTH VIA FOOD

But getting back to Dr Hay Dr Hay's *magnum opus* is his book "Health via Food," which has already been referred to as having been dedicated to his late employer, Mr Cabana The thesis developed in the book, briefly stated, seems to be that all pathologic states are due to errors in diet and "deficient

drainage"—the latter phrase accredited to William Arbuthnot Lane, who seems to be one of Dr Hay's tutelary divinities To overcome the "deficient drainage," Dr Hay, in various parts of his book, suggests the use of "Pluto Water" and then a change in the dietary habits of the patient "Acidosis," of course, looms large, and Dr Hay sees a definite "connection between acid-forming foods and disease" Thus, in the chapter on "The Role of Food," on pages 161 and 162, we are told

"Food is a direct cause of disease because it is the only source through which we can create these acids If acid causes disease, as there is not the slightest doubt, and if acid can come from nothing but food, then food is the one and only cause of disease, and how can we escape such conclusion?"

As we used to say when we studied Euclid Q E D There are, according to Dr Hay, four causes of acidosis (1) The use of too much concentrated protein, (2) the use of "refined, processed, denatured, emulsified, bleached, preserved, adulterated" foods, chiefly of the carbohydrate group, (3) the combining of proteins and carbohydrates, and (4) the retention in the colon of food residues beyond twenty-four hours following their ingestion Nearly every food faddist develops the obsession that proteins and carbohydrates should not be eaten at the same time, because, forsooth, proteins need acid for their digestion, while carbohydrates call for alkaline digestive juices The fallacy is based on that little knowledge that is dangerous Those who fall into it apparently conceive the human stomach as a large, open bag into which food drops, or is passed down, through the esophagus Just how the exponents of the theory that carbohydrates and proteins should not be eaten together can get around the fact that probably most of the common foodstuffs contain both proteins and carbohydrates, together with a certain proportion of fats, has never been explained

Facsimile (reduced) of the letter heads used at East Aurora when Dr Hay was Medical Director

adviser to his institution Dr William Howard Hay, "nationally known for the past decade as an authority on dietetics" In this connection, William Howard Hay's book "Health via Food," of which more later, is dedicated to Mr Cabana, whom Dr Hay describes as "one of nature's noblemen" Dr Hay further stated in his book that Mr Cabana, "not content to enjoy selfishly" his knowledge of the benefits of the right kind of food, determined to pass on the information to the public through a nation-wide educational campaign which he was going to carry on at "great financial risk" but a risk that he was willing to run "for his convictions" In a glowing peroration Dr Hay closes the dedication of his book to Mr Cabana with the statement "May his tribe increase and his shadow never grow less!"

POCONO HAY-VEN

Whether Dr Hay still holds Mr Cabana in the same high regard today as when he wrote his book (copyrighted 1929) may be doubted, for, as has already been stated, Dr Hay is no longer connected with the East Aurora concern but has opened what seems to be a competing institution in Mount Pocono, Pa In August, 1932, a Pennsylvania paper reported that Dr William Howard Hay and some hotel men had purchased the Mount Pleasant House at Mount Pocono and would open it under the name "Pocono Hay-ven" It was further stated that a Mr A E Stutzman, who had been associated with Dr Hay for the past six years, would be connected with him in this new venture Austin E Stutzman a year or two ago was the business manager of the East Aurora Sun and Diet Sanatorium of which William Howard Hay was medical director and Oliver Cabana, Jr, president

The Wilkes-Barre (Pa) Times-Leader for Dec 23 1932, reported that William Howard Hay, for the second time in two

Those who seek alcoholic stimulation—or narcosis—without the necessity of violating the law of the land, will be interested in the following brief paragraph from Dr Hay's book.

The heavy user of starches or sugars, if he combines these with either acid fruits or with meat or eggs can get up a very sizable jag from the alcohol generated in the stomach and intestine.

While Dr Hay recommends the use of Pluto Water as an evacuant, he is even more enthusiastic in his recommendation of the enema

There is but one harmless way to empty the colon, and this is with the daily [1] enema a measure that can be kept up indefinitely [11] without the slightest harm if conducted right. The use of the enema daily is a beneficent affair not in any way interfering with the normal function of the colon, and of great assistance to a colon hindered with its work.

Fasting, of course, is another of the panaceas suggested by many food-faddists, and here again Dr Hay runs true to type. In the chapter on this subject in "Health via Food," Dr Hay claims that he had one patient under his care who fasted for fifty-five days and lost sixty pounds in weight. During this period of nearly two months, the patient, a woman, is alleged to have continued her usual household duties, getting meals for the family, and "preparing the usual savory dishes." Under these circumstances one wonders just what scientific basis Hay has for stating unequivocally that the woman actually did fast for fifty-five days. In the words of a popular radio entertainer, "Vas you dere, Sharlie?"

It need hardly be said that Dr Hay is an anti-vivisectionist and has appeared on the platform under the auspices of the

eats fruit and raw vegetable juices for from one to two weeks and then switches to raw vegetable salads, vegetable broths, grains, baked potato and whole wheat bread. After this he is to take "the usual combination of foods as suggested by the Defensive Diet League." An enema of warm water in which bicarbonate of soda has been dissolved is to be given every night or, even better, both night and morning. And this is "Health via Food" by William Howard Hay, M D!

Correspondence

"MATERNITY WARDS IN GENERAL HOSPITALS" A REPLY

To the Editor—Dr J B DeLee states that the article "The Maternity Ward of the General Hospital," published in the January 7 issue of THE JOURNAL, is his reply to resolutions and editorials evoked by his recent publications on the subject. His reply consists of two principal portions

1 A series of quotations from various writers expressing their criticisms of modern hospital obstetrics as being more dangerous than home deliveries, and of the general hospital as being less safe, from the obstetric point of view, than the specialized maternity hospital

2 A collection by Dr DeLee and his co-author, Dr Siedentopf, from apparently all available sources, of a series of so called puerperal epidemics occurring in hospitals. They stress the fact that thirty-five such epidemics occurred in general hospitals, while only three such epidemics occurred in specialized maternity hospitals

The Cleveland Hospital Obstetrical Society, organized for the purpose of studying the obstetric mortality of Cleveland hospitals, has authorized the reply that follows

The sole purpose of studies of this type should be to arrive at facts which will enable us to provide better and safer care for women in childbirth. Dramatic denunciations, unless based on such facts, mislead the public, alarm women who desire to have children, by undermining their confidence in their medical advisers, and are productive of great harm

A detailed study by our society of every puerperal death in Cleveland for the last four years clearly demonstrates the startling fallacy of figures based on puerperal mortality. These figures include all deaths of women dying while pregnant or who have recently been pregnant, with the exception of proved cases of criminal abortion, which are classed as homicides. In other words, the term "puerperal death rate" includes, besides the deaths of women dying near term from a number of causes that can properly be grouped under the term "delivery death rate," a large number of other cases, of which the spontaneous and self-induced abortions, the ectopic pregnancies and the toxemias of the early months of pregnancy are the most numerous classifications. Considering the abortion situation alone, women tamper with themselves or go to midwives or disreputable practitioners. If they become infected they call their family doctor, who promptly sends them to the hospital. This is practically always a general hospital, as most maternity hospitals because they lack the facilities for proper isolation and care will not accept this type of case. The number of deaths from this classification alone is high and it adds greatly to the puerperal death rate of the general hospitals in comparison with that of home deliveries and especially in comparison with that of specialized maternity hospitals

Our society feels that the only criterion of the efficiency of a maternity division of a hospital is the delivery death rate of that division. The puerperal death rate of the hospital has nothing to do with the matter. We need ask only one question—namely, what percentage of the women delivered in this institution live and what percentage die. Our studies have brought out the following facts: Sixty per cent of Cleveland babies

Facsimile (reduced) of the card sent out announcing the opening of Dr Hay's new venture Pocono Hay-Ven

American Anti-Vivisection Society. Dr Hay is also opposed to vaccination, or, at least, he was so advertised by the Pittsburgh Health Club, an organization with which he seems to be popular. There have been four "doctors" listed among the officers of the Pittsburgh Health Club, one of them a dentist, one an optician, and the other two osteopaths. Dr Hay's opposition to vaccination may be better understood when we are told in his book that smallpox is nothing but "an effort to throw off waste matter."

In one of Dr Hay's articles allegedly written expressly for the bulletin of the Defensive Diet League already referred to, he tells of the wonderful results that he has had in treating progressive pernicious anemia. He states that he has "for twenty years been restoring these cases to normal after late stages were reached after eminent authority had abandoned hope of even a remission and even after the stage of coma had been reached." Dr Hay modestly explains that he does not claim to have cured a single case of this disease but only to have appreciated the cause and removed it. It appears that the cause of pernicious anemia is the use of refined denatured emulsified preserved adulterated food with a resulting intestinal stasis. In the same article Dr Hay outlines his treatment for pernicious anemia and after reading it one pictures the patient as exclaiming, "O death! Where is thy sting?" First of all the victim must use a large detergent purge or epsom or chamberlain's or a half-pint of concentrated Pluto Water or Epsom salt powders etc at a time taken fifteen to twenty minutes apart. After the preliminary treatment the patient

are born in hospitals. In this 60 per cent are found practically all the cases the status of which is not normal—cases of serious disproportion nearly all arrive at the hospital before delivery is complete, cases of cardiac incompetence, of renal insufficiency, cases of placenta praevia and of ablatio placentae, patients with serious toxemia or with actual eclampsia, patients with acute diseases such as pneumonia, are sent by their physicians to the hospital either before or sometime during labor. The result is that the patients who are delivered at home are a selected group of normal cases, who would have uncomplicated labors no matter where delivered. A striking majority of hospital delivery deaths are of patients admitted to the hospitals for known pathologic conditions, sent to the hospital because of its better facilities for saving their lives. A careful study of all puerperal deaths in Cleveland for one year (1931) showed that, of the women who died (from puerperal causes) in hospitals, 76 per cent were sent from the home to the hospital for known pathologic conditions. Women with infected abortions rarely die at home because they are sent to the hospital. Women with pathologic complications of pregnancy rarely die at home, because they are sent to the hospital, and yet the puerperal death rate of the hospital is compared with that of the home.

Dr DeLee's argument against general hospitals accepting obstetrics is based on his figures of puerperal epidemics. His ratio of epidemics in general hospitals to those in specialized maternity hospitals is 35 to 3, approximately 12 to 1. He makes no mention of the equally pertinent matter of the relative numbers of these institutions. According to the 1932 hospital number of *THE JOURNAL*, there were in 1931 in the United States, 3,258 registered general hospitals taking obstetric patients, and 145 registered maternity hospitals. This ratio is 22 to 1. In Dr DeLee's state of Illinois, 231 general hospitals take obstetric cases while 9 maternity hospitals are registered, that is, 24 to 1. Accepting Dr DeLee's own ratio of 12 to 1 as correct, the specialized maternities have twice as many epidemics of infection per hospital as do the general hospitals.

Dr DeLee has a great deal to say about "air-borne infection" and the deleterious influences at work in the general hospital. Apparently he believes that these mysterious influences are more potent than direct contact, since he ignores the fact that most maternities have no isolation quarters and that when they do they have no separate nursing staff to care for isolated cases. When a case of fever develops in the maternity division of a properly regulated general hospital, the patient and her baby are immediately removed to the medical or surgical wards in a different part of the institution, with a separate nursing personnel already established and functioning. This is physical separation and administrative separation carried out at once, without difficulty or embarrassment. When such a case develops in the average maternity hospital, the woman must either be simply isolated on the same floor with other maternity patients, without the benefit of a completely different nursing personnel, or be sent to another hospital as a case of puerperal sepsis. The psychologic resistance to this is, of course, tremendous. The admission that the hospital has a case of puerperal infection (with the necessity of plainly stating to the family that this patient cannot be kept in the same hospital with clean patients) is delayed from day to day, until the disease is clean cut and disastrous. In the meantime the contacts, both direct and indirect, are increasing and the chances that other patients will be contaminated are multiplied. Even an isolation pavilion does not dispel the thought that, if the case is not really puerperal sepsis, it is liable to become so if the patient is removed early to the infection pavilion. The general hospital has no such handicaps. The patient need only be placed in another part of the same building, not an infection pavilion, where a separate nursing force is already at work and functioning. No diagnosis of puerperal infection need be made

before the patient is transferred. If she has fever, that is sufficient reason for her removal, and the risk that she will become infected by such transfer is minimal as compared with specialized maternity hospitals.

It is the opinion of our group that the criterion suggested by Dr DeLee, viz., the "number of puerperal epidemics per hospital," is not a useful one. Neither is the classification of hospitals as specialized maternities and general hospitals accepting obstetrics of particular value. Our Cleveland tables show that the delivery mortality rates of these two types of institution are practically identical. In every instance the results depend on the management of the individual hospital, but there is no evidence of better delivery death rates in the specialized maternity hospitals.

The Cleveland Hospital Obstetrical Society does not desire to defend the hospital that treats maternity cases as a mere incident in its other work. Actual physical separation and entirely separate personnel are essential to safety. Isolated separate labor and delivery rooms are necessary. The laundry of the maternity division should never be mixed with that of the medical and surgical floors, so that sheets, pillow cases, and the like that have been used by infected surgical patients cannot be sent from the laundry to the obstetric floor. No hospital has the moral right, and none should have the legal right, to accept cases for delivery without making physical and administrative preparation for their safe care. We do contend, however, that the general hospital which makes adequate provision for the management and care of the obstetric patient under competent medical supervision is not only safe but has obvious advantages over the specialized maternity. The variety of its resources as to equipment and staff organization is likely to be much more complete. Lack of resources or carelessness in their use is inexcusable in any hospital when lives are at stake. If a hospital does not have adequate physical resources, it should not undertake the care of maternity cases.

The need is rather urgent that, in every large city, hospital obstetricians should organize themselves into a compact unit for the detailed study and classification of puerperal deaths. This subject should not be left to the pediatrician under the guise of child welfare, nor to the statistician who must accept written reports at face value. Obstetricians must themselves accept this responsibility for obtaining in detail the facts about each case, properly evaluating all the circumstances and classifying the reports accordingly. The group of obstetricians who have organized in Cleveland are learning much of value to themselves and hope soon to present valuable data to their colleagues. There has been entirely too much special pleading by those interested in fostering some particular conception on the profession. It will only be when there is a thorough study of the actual facts by a large group of disinterested obstetricians that the real merits of the problem will be determined.

THE EMBLEM OF MEDICINE

To the Editor—*THE JOURNAL* recently called attention to an infringement on the automobile insignia for physicians which it has been selling. The spurious emblem has two snakes entwined on the staff, instead of one. In 1931 an enterprising doctor presented a gold badge of office to the president of the Toronto Academy of Medicine as an official emblem portraying the sacred serpent being fed from a bowl. The official button of the American Medical Association is mostly snake-entwined staff. Why the snake and even so, why its continuance? Since the days of the Romans, the emblem of orthodox medicine has been the snake-entwined staff. Insignia are multum in parvo, but why continue to sail under such false colors?

What, then, should the insignia of medicine portray? We are living in a wonderful day and surely beyond our present possibilities, we must realize that the advanced thought being scrutinized critically by conservatism will be the advancement of tomorrow, that physiology will replace pathology, that the educated public has in mind "the maintenance of the structural integrity of the human body," that we must treat tendencies, not consequences, that nature works from within, and finally that the therapy which best supports and maintains function will accomplish most.

I wonder what a prize competition across America for a suitable emblem would bring forth? Some artist might line up the vitamins as a parade of the wooden soldiers, with room for more. Taking a different tangent, I could visualize Mr. Calory grading lettuce leaves and again suppose the sun kissing a biscuit. How about a solid phalanx of white corpuscles with daggers drawn standing four-square to Staphylo, Strepto, Diplo, and Pneumo? I hope no one suggests either malaria or maggots. I'm sure in the list would be a tray heaped up with tonsils old and young, interspersed with an odd appendix. If state medicine is in the offing, why not picture a galley slave smarting under the crack of the political whip?

After all, whatever the thought of the hour, the medical profession in all nations and all times might worthily be honored with the insignia of the Good Samaritan at the roadside, and the best that is in medicine as we enter 1933 can promise not only longer life but life more abundantly.

L. B. WILLIAMS, M.D., Toronto

GALACTOSE FOR DIABETIC PATIENTS

To the Editor—In THE JOURNAL, Nov. 19, 1932, appeared a communication by Dr. Harry Shay, which contained such incorrect interpretations of our report on galactose tolerance of normal and diabetic subjects (*J Biol Chem* 96:717 [June] 1932) that we find it necessary to submit the following rebuttal of Shay's statements.

Shay pointed out that, in our tests on normal and diabetic subjects in which 1 Gm. of galactose per kilogram of body weight was administered by mouth there occurred in the samples of blood collected one hour after ingestion an average drop of 36 mg. of fermentable blood sugar per hundred cubic centimeters for the normal subjects and an average increase of 22 mg. of fermentable sugar for the diabetic patients, making an average observed difference in fermentable blood sugar of 58 mg. per hundred cubic centimeters.

We object to the calculations made by Shay in the first place because they are mathematically incorrect, since they were calculated without taking into consideration the difference in the reducing powers of galactose and dextrose. We object further to Shay's figures because they were wholly unnecessary, as we published a complete mathematical analysis (table IV of our report) showing the amounts of fermentable sugar in each of the samples of blood collected from ten normal and ten diabetic subjects and called attention to the fact that there were increases in the fermentable sugar in the blood of the diabetic patients following galactose ingestion. We object still further to Shay's interpretation of our data because of the unsound comparisons he attempted to make. If he desired to examine our data with respect to fermentable sugar he should not have ignored the results we obtained when we fed fermentable sugar (dextrose). The most exact way to examine the tolerance of diabetic subjects for galactose as compared with dextrose (fermentable sugar) is to consider the response from the administration of both galactose and dextrose to the same patient on separate days, and not as Shay assumed to do by contrasting the results obtained by the administration of galactose only to different subjects.

The results we obtained following the ingestion of the same dosage of galactose and dextrose by the same patient afford striking evidence that the diabetic subject has a higher tolerance for galactose than for dextrose. Our report shows that, when dextrose was fed, the blood sugar curves showed typical diabetic responses with maximum elevations at the end of two hours, and when galactose was fed the total blood sugar curves did not go nearly as high and showed a sharp return toward the preingestion level at the end of the two-hour period. Following galactose ingestion the average maximum increase in blood galactose was 47 mg. per hundred cubic centimeters and the average maximum increase in total blood sugar was 87 mg. per hundred cubic centimeters. These figures mean that there was an average maximum increase in fermentable blood sugar of 40 mg. per hundred cubic centimeters following galactose ingestion in our series of diabetic patients. When the same dosage of sugar in the form of dextrose was fed, there resulted an average maximum increase in fermentable blood sugar of 155 mg. per hundred cubic centimeters in two hours (from table II of the data in our article). Assuming the criterion proposed by Shay, namely, the increase in fermentable sugar in the blood, it is to be noted that there was almost four times as great an increase in the fermentable sugar of the blood of our diabetic subjects when fed dextrose as when galactose was fed. Or assuming as criteria either the increases in total blood sugar or the increases in blood galactose as compared with the elevation of the blood dextrose, our data show a strikingly greater tolerance for galactose than for dextrose by diabetic patients.

The statements set forth by Shay concerning the importance of the liver in galactose metabolism are really arguments in favor of the premise he assumes to oppose. It certainly requires no demonstration at the present time to show that diabetes mellitus is a disease involving the pancreas and not the liver. Since it has been shown that the liver has an important role in the metabolism of galactose and the diabetic patient apparently has a normal glycogenic liver function, the question remaining for demonstration of the tolerance of the diabetic for galactose is what part the pancreas plays in the metabolism of this sugar. This is exactly what our report considered. The significant evidence presented by us was that (1) following galactose ingestion there was no greater galactosemia, and essentially no greater saccharemia in diabetic patients than occurred in normal subjects, (2) comparative tests of galactose and dextrose feeding to diabetic patients showed the usual intolerance for dextrose and an almost normal response to galactose, and (3) insulin is not involved in the anabolism of galactose.

The argument Shay makes that "galactose as such is not utilized as a source of energy by the animal economy" has no significance. It makes no difference whether galactose is metabolized as such or is converted to some other substance (probably glycogen) before undergoing catabolism. The essential fact remains that galactose is utilized, and there is plenty of evidence in the literature for this.

Since sending our paper to press there have appeared in the literature two reports which have an important bearing on this question. Kosterlitz and Wedder (*Klin Wchenschr* 19:553 [March 26] 1932) have reported that galactose fed to diabetic patients in doses of from 10 to 20 Gm. from two to four times daily is antiketogenic, is protein sparing, and results in less glucosuria than occurs when corresponding amounts of dextrose are fed. Deuel, Gulick and Butts (*J Biol Chem* 98:333 [Oct.] 1932) report Galactose has been demonstrated to possess a greater ketolytic action than glucose in the human, both on ketosis due to fasting and on that produced by an exclusive protein diet. This superiority is exhibited not only in the larger drop in ketonuria but also in the more prolonged decrease that results. Likewise there is some evidence

to indicate that a more pronounced nitrogen-sparing action follows the ingestion of galactose" These reports add further weight to the suggestion in our report "that galactose might be made a valuable adjunct to the diet in the clinical management of diabetes mellitus"

We fully realize that the way to settle such problems as these is by laboratory experiments and not by discussion But we claim the right to object to incorrect interpretation of our experimental work, and we maintain that such an important possibility as the improvement of the diet of the diabetic patient merits an attitude of open-mindedness Of course the possibility of galactose feeding to diabetic patients needs further proof We are studying this problem with depancreatized dogs, and clinical trials of galactose feeding are being made in clinics where careful biochemical control is available Galactose feeding to diabetic patients is still in the experimental stage, and until conclusive laboratory and clinical evidence on galactose feeding is produced, we seriously urge physicians not to consider the use of this sugar

ERGOTAMINE TARTRATE IN PRURITUS

To the Editor—In THE JOURNAL, February 4, page 328, Drs Ernstene and Banks record their experience with ergotamine tartrate as an antipruritic agent and refer to my clinical note (THE JOURNAL, Nov 14, 1931, p 1563) on the subject The lack of uniform results with this drug in the treatment of pruritus in urticaria and other dermatoses has already been recognized

It has been pointed out that ergotamine tartrate exerts its depressant action on the sympathetic nervous system, the tonus of which is heightened The prompt relief from pruritus obtained in patients with jaundice and azotemia suggested the existence of a sympathicotonia in these individuals The metabolic changes in the skin in these conditions provokes the increased nervous irritability

In my experience to date, and in that of physicians and clinics which has been brought to my attention, the claim for the drug has been confirmed In about 75 per cent of patients suffering with pruritus associated with jaundice or azotemia, treatment as described has brought relief I stress here that results may be expected especially in this selected group of patients with pruritus

S S LICHTMAN, M D, New York

INFARCTS OF THE KIDNEY

To the Editor—From reading the paper by J Dellinger Barney and E Ross Mintz entitled 'Infarcts of the Kidney' (THE JOURNAL, January 7), the reader would get the impression that no exact knowledge on the subject existed from the time of the classic contribution of Traube in 1856 until the paper of Dr Ashner in 1922 The authors point out that "the literature is comparatively scanty" In a paper entitled "Clinical Manifestations of Hemorrhagic Renal Infarct Review of Literature and Report of a Case," published in the *Archives of Internal Medicine* in April, 1908, I reviewed the then existing ten cases in the universal literature, to which I added my own case I may be pardoned an author's vanity in expressing the belief that my paper possesses an historical interest because it was the first in the English language and the first in American literature to deal with the subject Associated in the case were two brilliant names in American medicine—that of the late Dr Bertram W Sippy, who was the consultant and that of the late Dr John B Murphy, who was the surgeon Dr Everts Graham was the intern in the case and assisted in the postmortem examination In my

paper the views of Traube and of von Leube were presented, the clinical manifestations of infarcts were clearly described, and the possibility of a diagnosis in vivo was particularly stressed

A second paper dealing with histologic studies of the two kidneys was presented before the Chicago Pathological Society and subsequently published in the *Transactions of the Chicago Pathological Society*, Feb 8, 1909 The specimens were presented to the pathologic laboratory of Rush Medical College Later contributions have added more cases but nothing that has not already been clearly stated in the classic contributions of Traube and von Leube

GEORGE HALPERIN, M D, Chicago

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed Every letter must contain the writer's name and address, but these will be omitted, on request

SENSITIVITY TO COLD

To the Editor—A woman, aged 33, well developed and well nourished, whose blood pressure is 140 systolic, 70 diastolic, has retroflexion of the uterus She is irritable If she goes out in cold weather, her face and hands swell When she goes into the house, they return to normal Eating ice cream in the summer causes her tongue and lips to swell and something seems to choke her Putting her hands in cold rinse water causes them to swell to the water line Otherwise the patient is normal No laboratory tests have been done except on the urine Please omit name

M D, Illinois

ANSWER—Probably this patient is sensitive to temperatures between 5 and 15 C (41 and 59 F) wherever they are applied, although the exposed parts may be more tolerant than parts under the clothing, which are more protected from low temperatures The breathing of cold air affects the conjunctiva, nasal membranes and bronchial membrane just as cold of certain degree will affect the skin The drinking of cold water will affect the tongue, mouth, esophagus and stomach in the same way Exposure of a gross area of the skin to cold between 5 and 15 C will almost certainly cause a generalized shock reaction similar to pollen shock This is dangerous and necessitates the immediate use of epinephrine Accidental exposure to cold moist wind just above freezing, or swimming in cold water, is dangerous

Patients of this sort can be given relative tolerance to cold by rubbing increasing areas of skin with ice at frequent intervals This gives them localized and generalized tolerance and can be pushed to a point at which they can be comfortable if they avoid unnecessary exposure to cold

The patient should be acquainted with this condition, otherwise he is likely to get into a situation in which overexposure is unavoidable

In recent literature it is mentioned that the condition is more frequent in women than in men and that in some it seems to be connected with the pelvic organs In spite of this, the finding of a retroflexed uterus is probably unimportant

The patient should seek a warm climate to live in and avoid cold drinks and cold foods The first description of the condition appears in an article by W W Duke on "Urticaria Caused Specifically by the Action of Physical Agents" (THE JOURNAL, July 5, 1924, p 3), and there is a review of more recent literature on the subject by the same author in the *Archives of Otolaryngology* (November, 1932, p 721)

USE OF IODIDE OR COMPOUND SOLUTION OF IODINE

To the Editor—Where the iodides are indicated, is it not preferable to use compound solution of iodine (Lugol's solution) instead? I have been advised that this solution is less apt to cause iodism and does not possess the harsh taste of the iodides I would greatly appreciate your opinion on this matter Please omit name

M D New York

ANSWER—There is no doubt that the taste of compound solution of iodine (Lugol's solution) is a great deal harsher than that of iodide and that its irritative effects are likewise greater Compound solution of iodine is a solution of iodine (5 per cent) in a solution of potassium iodide (10 per cent) It may contain free hydroiodic acid There is reason to believe that in point of fact sodium or potassium iodide is capable of producing the

same effects as compound solution of iodine even in hyperthyroidism, as is attested by a number of observers. If this is the case, the administration of compound solution of iodine is a definite error in administration, especially in the very sensitive hyperthyroid individual. So far as can be determined, the reason for its use in this condition is merely historical. It happened to be first used for this purpose, and it seems that, in view of good effects secured by it, clinicians are averse to making the change, which probably should be made.

RECURRENT MASTOIDITIS

To the Editor—How often is it necessary to perform a secondary operation in infants who have had mastoidectomies for acute mastoiditis? Please omit name. M D New York.

ANSWER—It is difficult to quote accurate figures as to the number of recurrences of mastoid symptoms in infants who have had mastoidectomies performed previously for acute mastoiditis. Every otologist with large experience sees from time to time a breakdown of an apparently well healed scar following an acute attack of otitis media. The second attack of mastoiditis should be no more surprising than the first, and a previous operation should not be expected to prevent a new and fresh attack. If by the question was meant how often it is necessary to reoperate in infants following mastoidectomy because the first operation did not heal quickly enough and satisfactorily enough, it is true that from time to time procedures such as curettement of the wound, freshening the edges of the skin margins and resuturing are part of the experience of every operator.

ERYTHEMA NODOSUM

To the Editor—Please give the present status of the etiology, pathology treatment and other pertinent information you may have concerning erythema nodosum. I have been associated with Dr F C Pinkerton of the American Hospital at Guatemala in the treatment of several cases of the disease. We have been treating the cases with an autogenous vaccine made from the bacteria isolated from the blood stream. The bacteria were of the streptococcus group. The results have been satisfactory so far with the vaccine therapy in addition to the removal of the focus of infection. In our limited library facilities and our limited number of periodicals available we have not been able to find mention of this method of obtaining the causative organisms. Has this work been previously performed by other investigators? We are desirous of receiving your information at an early date in order that we may act accordingly in our desire to publish our results.

Director of Biological Laboratories W H GAUB, Guatemala.

ANSWER—These results in the isolation from the blood stream of an organism belonging to the streptococcus group in cases of erythema nodosum are in accord with the work reported by Rosenow (The Etiology and Experimental Production of Erythema Nodosum, *J Infect Dis* 16 367, 1915), who demonstrated diphtheroid-like streptococci in excised nodes in human cases, and who isolated from these nodes, from the blood and from the throat and infected teeth a pleomorphic, diphtheroid-like streptococcus which had elective affinity on isolation for the subcutaneous tissues of dogs, rabbits and guinea-pigs when injected intravenously. The streptococcus morphology became dominant on animal passage, and in the experimentally produced erythematous, hemorrhagic nodes this form was found in sections.

SEXUAL DESIRE AND POTENCY AFTER PROSTATECTOMY

To the Editor—What percentage of men retain sexual desire and potency after modern prostatectomy operations? The only definite information I have at hand is contained in a paper by Hinman (*Arch Surg* 4 154 [Jan] 1922) in which he relates that of fourteen patients six retained sexual desire after perineal prostatectomy, five had sexual intercourse and four of the latter had a seminal discharge. In a later series of twelve cases, normal sexual life was resumed in three.

J L KAINS M D Seattle

ANSWER—It is necessary to distinguish between sexual desire and relative and actual potency. Libido may be present without erection; erection may be produced allowing insertion of the penis without orgasm and ejaculation and finally the proper sexual act may be possible.

The value of available statistics is somewhat impaired by the fact that as a rule they are compiled by taking the patient's statements as their basis. The true state of affairs can be judged only by interviewing the female partner and by examining the ejaculatory product if it is available. Under such premises one comes pretty close to the truth by stating that about 25 per cent of the patients retain occasional sexual desire, 15 per cent show relative potency and true potency is maintained in 5 per cent.

POSITIVE SPINAL FLUID WASSERMANN TEST

To the Editor—Kindly inform me whether a positive spinal fluid Wassermann reaction can be obtained in any other condition than syphilis and if so, please inform me in what diseases.

MAXIMILIAN MALINA, M D, Chicago

ANSWER—Positive Wassermann reactions with spinal fluids in conditions other than syphilis are rare. Such reactions have been described in isolated cases of brain tumor, influenzal encephalitis and infectious meningitis. An examination of the League of Nations' Health Committee report of the Montevideo (1930) conference reveals three, one and one positive spinal fluid reactions, respectively, given in cases of dementia praecox and idiocy by three Wassermann methods in a group of 147 nonsyphilitic cases. A fourth Wassermann method, that of Wyler (also the Kahn reaction), did not give false positives in this group of cases. A comparison between blood serum and spinal fluid results at this conference indicates that even Wassermann methods that show a marked tendency toward false positive reactions with blood serum give but rarely such reactions with spinal fluid.

EFFECTS OF CANNABIS

To the Editor—I have been hearing about the smoking of cigarettes dipped into or medicated with fluid extract of Cannabis americana. I can find nothing about the use of the drug by addicts. What is its immediate effect? What are its late effects? What is the minimum lethal dose? In what way does it differ from or resemble muggles in its action? While in Louisiana I was told that the use of marihuana causes dementia. Is this true? Please omit name.

M D, Illinois

ANSWER—The effect of Cannabis americana is the same as that of Cannabis indica, and, of the effect of the latter, the books are so full that it is hardly necessary to detail them here. It must suffice here to say that cannabis, at the height of its action, usually produces hallucinations, with or without euphoria, and that these are followed by a deep sleep. Its most marked after-effect is the liability to the establishment of a craving for the drug, the habitual use of which undermines the intellectual qualities and the social value of the victim and leads to general physical deterioration. It is stated that smokers nearly always become imbecile in time. The minimum lethal dose is unknown, no fatalities having been reported in man. In view of the fact that one dose may kill one dog that has no marked effect on another, one must admit the possibility of a lethal effect on man. In view of what has been said, it must be admitted that "marihuana," which is merely another name for Cannabis indica, may cause dementia.

ALBUMIN IN URINE AFTER PROSTATIC MASSAGE

To the Editor—What is the significance of (1) urine, normal as voided but showing albumin directly after prostatic massage with no other abnormalities? (2) urine, normal as voided but showing albumin and bacteriuria after prostatic massage with no other abnormalities? Kindly omit name.

M D New York.

ANSWER—1 Urine, normal as voided, but showing albumin directly after prostatic massage, would obviously indicate that the source of the albumin is in the male secretions. The prostate and also the seminal vesicles contain albuminous secretion. A prostatitis or vesiculitis would produce a pyuria and bacteriuria as well as an albuminuria. In urethritis there may also be an albuminuria due to pus cells and bacteria.

2 Urine, normal as voided, but showing albumin and bacteriuria after prostatic massage, would indicate the presence of an acute or chronic prostatitis. In such cases gonorrhea and tuberculosis must always be considered and the specific organisms sought. The other causes are simple pyogenic infections with the staphylococcus, streptococcus, colon bacillus and diphtheroids.

SYNOVITIS WITH EFFUSION

To the Editor—For about three months a man aged 28 has had a chronic synovitis with effusion in one knee. There is slight pain but considerable effusion. He does not recall injuring the knee and states that it gradually began to hurt and swell. He has no fever at any time except after some vaccine treatment. What is the possible cause for this? I would appreciate some suggestions regarding treatment. He has already had heat rest, counterirritants and bacterial vaccines with practically no improvement.

M D Indiana.

ANSWER—The following etiologic factors should be considered and eliminated if possible: infection, injury, exposure, metabolic disturbance, occupation, allergy and neoplasia. The correspondent does not state whether the effusion is constant or intermittent. He does not state whether aspiration has been performed for diagnostic or therapeutic reasons. Under treat-

ment, one may suggest rest in bed, application of moist heat during the day and dry heat at night, with applications during the day of radiant heat, also gentle massage, diathermy and a splint. One of the most important considerations is the maintenance of tonicity of the quadriceps extensor muscle, which should be accomplished by means of active and resistive exercises and electrical stimulation. Diet may be important. A compression bandage may be used. Climate may be a factor. The effect of vaccine may be considered a reaction. If so, the dose should be cut to one half or one tenth. Vaccine should be given as a desensitizing measure, therefore, the smaller the dose, the better. There has been some interesting recent work done by Thomsen of Lincoln, Neb., on the use of Pregl's solution of iodine injected into the knee joint, for this condition.

PAIN IN THE NECK

To the Editor—I have a patient who has been unsuccessfully treated over a period of three years by several other physicians for a pain in his neck. He is 60 years old. There is a moderate hypertension. The pain begins at the seventh cervical vertebra and runs up the right side of the neck posteriorly then round the right side of the head above the ear, and then across the forehead. There is constant headache. Some soreness is also complained of in the muscles of the left side of the neck posteriorly. Moving the head sideways is quite painful but forward and backward movement is not. There is a slight papular eruption in the line of pain just anterior to and above the right ear. Please omit name.

M D, Michigan

ANSWER—The data supplied are insufficient. One would like to know more concerning the onset and whether or not there was an injury, focal infection, metabolic disturbance or exposure to extremes of hot and cold or dryness and moisture. One should know the result of an examination by means of anteroposterior and lateral roentgenograms of the cervical spine. No mention was made of syphilitic infection or the Wassermann reaction.

The first reaction to this question would lead one to a diagnosis of osteo-arthritis of the cervical spine with cervicobrachial neuritis. The importance of the eruption is questionable. As is well known, herpes may appear along the distribution of the nerves involved in neuritis.

Under treatment, one would suggest any or all of the following:

1 A search for foci of infection, especially in the teeth, throat, sinuses and the gastro-intestinal, genito-urinary and respiratory tracts.

2 A thick, cotton collar such as described by Schanz, which may be of real benefit.

3 The consideration of diet, medicine and vaccine therapy.

4 Recumbent treatment, including head traction with the head of the bed elevated.

5 Physical therapy including radiant heat, gentle massage and diathermy. If diathermy increases pain, it should be discontinued.

6 A brace or a cast.

ASCARIS INFESTATION

To the Editor—I have had a patient suffering from infestation with nematode ascarides under my observation for about three months. He passes from six to twelve parasites daily, which are about 2 inches in length and one fourth inch in width. They are flat and white in appearance. Examination of the feces reveals many ova, which are egg shaped and appear to have a definite smooth shell. I have given 4 grains (0.26 Gm.) of santonin in divided doses daily for a period of three days, followed each night by a saline purge. I have also administered 12 minims (0.75 cc.) of oil of chenopodium in divided doses daily followed by a saline purge or castor oil. Thus far my therapy has been ineffectual in eradicating the parasites. If you can suggest any form of treatment, I shall greatly appreciate it. *DORSEY S. LENZ, M.D., Midwest Wyo.*

ANSWER—Santonin is almost specific for *Ascaris* infestation. A dose of from 0.03 to 0.06 Gm, especially when given in castor oil in the morning, if no food is eaten for from two to four hours afterward, usually results in expulsion of the worms. If they are not expelled, another dose of castor oil should be given and the patient kept on a light diet the remainder of the day.

Though carbon tetrachloride is considered less reliable against *Ascaris* than oil of chenopodium or santonin, it might be tried in a dose of from 2 to 3 cc for an adult, given with 50 cc of a saturated solution of magnesium sulphate.

In view of the fact that the nematodes are round worms and the worms passed are described as flat the diagnosis might well be questioned and this might explain the failure of treatment, as tapeworm infestation requires different remedies from those used against the round worms.

CHRONIC CHOLECYSTITIS WITH STONE IN COMMON DUCT

To the Editor—A white woman, aged 52, 5 feet (152 cm) tall, weighing 110 pounds (50 Kg), has been under my care for a year and a half on account of attacks of what appears to be an acute biliary colic. She was operated on eight years ago, at which time surgical drainage was done. About six months later a cholecystectomy was done. She has had frequent attacks of colic since then. I saw her first in June, 1931, and from that time until December, 1931, she had attacks about two months apart. They are quite severe causing much vomiting. At the time her epigastrium and right hypochondrium are exceedingly tender to palpation. It required morphine sulphate, from $\frac{1}{4}$ to $\frac{1}{2}$ grain (16 to 32 mg), with atropine sulphate, $\frac{1}{100}$ grain (0.6 mg), hypodermically, to give relief. Following the attack in December, 1931, I instructed her to take tincture of belladonna, 15 drops three times a day before meals, as soon as she felt the first slight pain, which was a warning of the onset of another attack. She did this and until November, 1932, or nearly a year, had no difficulty. I have tried tincture of belladonna on four other patients in similar circumstances and it has worked well. Is there anything better to do for these people who haven't been given permanent relief by surgery? Is it possible that this patient is having stones form in the hepatic ducts or common duct? She is never jaundiced, and the stools are only moderately light in color at the time of the colic. Please omit name.

M D, Minnesota

ANSWER—The persistence of attacks of abdominal pain that are obviously biliary colic, following cholecystectomy, points to obstruction in the hepatic or common bile ducts. The cause of such obstruction is almost always one or more stones. It is generally held by surgeons that such stones do not form in the ducts following cholecystectomy but are overlooked at the time of operation. The possibility of operative or inflammatory damage to these ducts (hepatic, common) must, of course, also be considered in this patient, who has had two operations. It is probable that latent jaundice, as demonstrated by a high Van den Bergh test, could be shown to be present during the height of any severe attack. Belladonna does lessen the severity of such attacks and at times seems to control them. However, since there has been a lapse of eight years, it is very unlikely that this patient will obtain permanent relief from anything but surgical intervention. If this is not done, persistent cholangitis will ultimately cause serious harm to the liver.

IMMUNIZATION AND RELAPSE IN SCARLET FEVER

To the Editor—1 How common is the requirement to have pupils in hospital training schools immunized against scarlet fever? 2 What is the incidence of relapses in scarlet fever? I have seen two cases within the year the initial symptoms of sore throat, rash and fever have been repeated with marked intensity within a week of the initial infection. The second case occurred following the use of two bottles of scarlet fever antitoxin. The rash was not urticarial but punctate and typically scarlet rash with return of sore throat and tongue signs.

ROY J. WARD, M.D., Worcester, Mass.

ANSWER—1 The majority of training schools where pupil nurses receive training in contagious diseases require immunization against scarlet fever if Dick tests indicate susceptibility, and many hospitals where there is a large pediatric service also require it.

2 Less than 1 per cent. The statement that two "bottles" of scarlet fever antitoxin were used does not give information as to the dosage of antitoxin employed. Some health departments which put out scarlet fever antitoxin in bottles are distributing for therapeutic use doses of antitoxin no larger than the amount commonly employed for a prophylactic dose and considerably smaller than the usual therapeutic dose of scarlet fever antitoxin.

YEAST AS A LAXATIVE

To the Editor—In THE JOURNAL, Sept. 17, 1932, under the heading of Queries and Minor Notes, the statement is made that yeast is a laxative and that there is no essential difference, in their effects, between fresh or live yeast and dried brewers' yeast. The Fleischmann people make the claim that their yeast "softens the waste matter of the intestines," and the inference is that this is accomplished by reason of fermentation. The further inference is perhaps, that fresh yeast causes the formation of gas, which aids the process of evacuation. Dried brewers' yeast, lacking the fermentative quality, would therefore not operate in this manner. I should like to know whether the vitamin B complex in itself is a laxative irrespective of whether it is found in fresh yeast, dried brewers' yeast, wheat germ or other sources in sufficient quantities and whether there is authoritative information on dried brewers' yeast as a constipation corrective. If so where can I find the material? Please omit name.

M D, Illinois

ANSWER—Amy L. Daniels (*Am J Dis Child* 23:41 [Jan 1922]) produced diarrheal stools with killed yeast (from 3 to 10 Gm) in babies. On the whole, yeast is a rather uncertain laxative, and there are some authors who have not noted marked laxative properties when they used yeast as nitrogenous nutriment, though others have found that the looseness of the

bowel liable to be produced in some cases interfered with the nutritive value of the yeast. Yeast has even been used in cases of diarrhea with alleged benefit. There is general agreement that, in the constipation of vitamin B deficiency, yeast—whether dried or fresh—is especially efficacious.

ARTHRITIS DEFORMANS IN AGED

To the Editor—A woman patient aged 81, has had a steadily advancing case of arthritis deformans for ten or twelve years. Practically all the joints are now immobilized though she has partial use still of her hands and arms so that she is able to feed herself and do a few other things with difficulty. Treatment has been mainly palliative, except that diathermy was given at frequent intervals for a year, apparently without effect. For the intermittent pain in the joints I use dry heat, gentle massage and counterirritants locally with sedatives by mouth, usually phenobarbital or a related barbitol. At her age (she is much afraid of pain and is opposed to any strenuous methods of treatment) and considering the chronicity of the condition is there much hope of arresting the advance of the process to the joint so as to preserve what little motion she now has? Is there anything further than what I have mentioned that could be done to control pain? Please omit name.

M D, Massachusetts

ANSWER—Diathermy is not always helpful in these cases, and in some it is actually harmful. There is not much hope of arresting the advance of the process in the joint, although this statement must be made with reservations. The various factors that should be considered in the treatment are the clearing up of foci of infection, the application of moist, dry and radiant heat, fresh air and sunshine—which may necessitate change of climate, the use of ultraviolet radiation, small doses of acetylsalicylic acid and amidopyrine and vaccines. One should attempt to determine the smallest dose that will keep the pain under control. This may necessitate hypodermics every four days, which period can be lengthened to seven, ten or fourteen days rather than change the dose of the vaccine.

DELAYED DESCENT OF TESTIS

To the Editor—A boy aged 11 has bilateral migrating testicles. His parents have noticed the condition for only the past two or three years and state that he was apparently normal up to that time. At present the testes are firm and about the size of small lima beans. They can be pushed into the scrotum easily but on release of pressure immediately return to the lower part of the inguinal canal. The child is normally developed physically and mentally. Can the condition be corrected without surgical intervention by means of a truss or other support? If a truss is worn for a year or more will the testes again be drawn up on removal of the truss? What is the prognosis as to sterility at the present time? Will a testis develop normally if it is possible to keep it in the scrotum with a truss? Please omit name.

M D Illinois

ANSWER—One important fact has been omitted: whether the child has any evidence of hernia. Granted that there is no hernia on either side, there would be no reason to advise a truss. It has been well established that when the testes can be readily pushed into the scrotum they will develop normally and should migrate to the scrotum within the next three or four years. A truss will not hasten the descent. Although the testes would seem to be a trifle smaller than normal at the present time, they will probably develop rather rapidly toward puberty and there is no reason to suspect sterility. Should a testis remain permanently in the inguinal canal it will not develop spermatozoa, as has been shown experimentally by Moore.

ONYCHOMYCOSIS

To the Editor—A patient aged 40 whose general health is good has an ulceration surrounding and beneath the nails of the third, fourth and fifth fingers. The Wassermann and Kahn reactions are negative. All foci of infection have been eliminated. A diagnosis of onychomycosis has been made by several physicians and concurred to by a dermatologist. Please advise proper treatment. Please omit name. M D Wisconsin

ANSWER—For onychomycosis Whitfield's ointment (6 per cent of salicylic acid and 12 per cent of benzoic acid in petrolatum or ointment of rose water) applied once daily has cured some cases and has the advantage of not discoloring the nails. Roentgen rays unfiltered or lightly filtered through aluminum, one-fourth erythema dose once a week for from eight to twelve doses clear up many cases. A weak solution of iodine 1:500 in 2 per cent water solution of potassium iodide may be used as a wet dressing or bath several times a day. If these measures fail the nail can be removed surgically and the wound dressed with 5 per cent iodine ointment for one week, then with boric acid ointment for the remainder of the time. The nail grows out again in about five months. The condition is discussed by G. C. Andrews (Diseases of the Skin, Philadelphia W. B. Saunders Company 1930 p. 577).

USE OF LEMON JUICE FOR ACIDIFYING MILK IN INFANT DIET

To the Editor—When lemon juice is used to acidify milk for infant feeding will there be an adequate amount of vitamin C in the milk so prepared that orange and tomato juice may be omitted from the diet? I have a patient who has considerable gastric disturbances when orange or tomato juice is given even in small amounts. Is lemon juice or citric acid often used to acidify evaporated milk? Please omit name.

M D, Georgia

ANSWER—If lemon juice in sufficient quantity is added to the milk formula, the infant may receive an adequate amount of vitamin C to protect him against scurvy. Orange juice and tomato juice may then safely be omitted from the diet.

The antiscorbutic vitamin is probably the least stable of all, being easily destroyed by moderate degrees of heat, and is also readily damaged or destroyed by drying. Vitamin C is also sensitive to aging, particularly when it is subjected to an alkaline or neutral medium. It has been shown that lemon juice, if stored in a cold place for two weeks, would lose much of its vitamin C potency. It would seem, then, that if fresh lemon juice in sufficient amount is added to the daily formula and not subjected to too great heat, a sufficient antiscorbutic potency will be present to protect the infant against scurvy.

In a recent article, Oscar Reiss (*Arch. Pediat.* 49:170 [March] 1932) reports the successful use of lemon juice in evaporated milk in a series of infants under 1 year of age.

POSSIBILITY OF DEFORMED CHILD AFTER CURETTEMENT OF PREGNANT UTERUS

To the Editor—Two months ago a patient was curetted for uterine bleeding which began thirty-four days after the last regular menstrual period ceased. A few clots and endometrium were removed from the uterus after which the bleeding stopped. Without having an intercourse since the operation the patient is now about three and one-half months pregnant. Do you think there is any likelihood of the mother having a deformed baby as a result of the operation? Please omit name.

M D, Georgia

ANSWER—Accidents such as the one described have occurred many times. In nearly all instances the fetuses whether expelled prematurely or delivered at full term, have been normal. In these cases the gestation continues after the curettage because the ovum escapes the process of scraping. If the ovum is damaged, it is nearly always expelled. Such accidents rarely occur in a gestation with a duration of more than five or six weeks because after this time the fetal sac is too large to be missed except through gross carelessness. If, in the case cited, the pregnancy was only from twenty to twenty-eight days old at the time the curettage was performed, it could easily have been missed during the operation. The ovum was undoubtedly unharmed in this case because little tissue was obtained. Hence there need not be any fear of a deformed baby as a result of the operation.

ABSORPTION OF EPINEPHRINE AND EPHEDRINE IN THE STOMACH

To the Editor—I am reviewing the literature on sinus disease in children. I have been using diluted solution of epinephrine (from 1:4000 to 1:8000) in physiologic solution of sodium chloride. To assist me will you please give me the following information: What is the fate of the epinephrine hydrochloride solution after its gravitation into the stomach? Is any of it absorbed or is it destroyed? Similarly the fate of the ephedrine sulphate solution. Please omit name.

M D New York

ANSWER—When swallowed, epinephrine produces practically no effects. It usually does not pass through the alimentary mucosa though, in exceptional instances, marked reactions may occur. Ephedrine on the other hand, is absorbed and produces its systemic effect even when given by stomach.

DOSAGE OF CAFFEINE

To the Editor—I should like to ask about the dosage of caffeine. The teaching was that the dosage is from 1 to 2 grains and that 4 or 5 grain doses had caused serious poisoning. Today some men inject intravenously with impunity 15 grains of caffeine at one time and little is heard about caffeine poisoning. Please inform me what the most desirable dose of caffeine is for quick stimulation according to modern research. Please omit name and address.

M D California

ANSWER—The doses given in the textbooks are merely average doses. In view of the fact that tea drinkers may take 0.6 Gm. of caffeine daily, a dose of 1 Gm. or 15 grains would not be excessive for "quick stimulation" excepting that it may, along with this, produce restlessness and insomnia.

EFFECTS OF ELECTRIC WELDING ON BLOOD

To the Editor—Will you kindly give me information concerning the effect of the occupation of electric welder on the blood? Just what are the reasons of insurance companies for considering this occupation extra hazardous? Please omit name

M D, Wisconsin

ANSWER—Actual experience on the part of insurance companies has revealed that death rates among electric welders are well above those for the working population in its entirety

A number of hazards are associated with electric welding work. Among others are electric currents, chemical rays, leading to intra-ocular inflammation and dermatitis, metal fumes, notably lead, and hampered vision at the end of the work period, owing to previous exposure to intense light. Skin cancers are said to be high in this occupation. Also respiratory diseases, many of which are related to metal fumes, which serve as irritants to the respiratory tract.

The occupation of electric welding, in the absence of electrocution, is not known to pave the way for any specific changes in the blood. If however, such work involves exposure to lead or arsenic and their corresponding diseases are developed, characteristic changes in the blood may take place, such as the anemia and the basophilia of lead poisoning.

Elaborate protective devices are commonly provided the electric welder, notwithstanding which some risks apparently exist.

USE OF DICK TEST AND IMMUNIZATION FOR SCARLET FEVER

To the Editor—Please give the present status of scarlet fever in regard to prophylaxis and treatment. Is it advisable to use the Dick test in all cases before giving prophylactic treatment?

NEVIL M GARRETT, M D, Brodhead, Ky

ANSWER—Active immunization against scarlet fever is in general use. The employment of scarlet fever antitoxin in the treatment of scarlet fever is generally recommended. It is advisable to use the Dick test before immunizing against scarlet fever.

EFFECTS OF WATER ON DIGESTION

To the Editor—Has any experimental work substantiated the claim that the drinking of water in small amounts throughout the day has a more beneficial effect on nutrition than the drinking of the same total quantity in comparatively large amounts? Please omit name.

M D, Minnesota.

ANSWER—Experimental work designed to answer the specific question has not been done. Older work seems to show that the ingestion of large quantities of water promotes digestion (Hawk) partly by dilution of the blood (Sutherland, Ivy), partly by throwing into action (by increased intragastric pressure) the mechanical phase of gastric secretion (Ivy).

USE OF QUININE AS PROPHYLACTIC—CHLORBUTANOL AS PRESERVATIVE

To the Editor—1. It is customary for white people in this country (West Africa) to take a prophylactic dose of quinine once a day. Is there any reason to believe that the sulphate is more deleterious to health than the hydrochloride? 2. Is there any objection to adding a small amount (0.5 per cent) of chlorbutanol as a preservative to a solution of antimony and potassium tartrate for intravenous injection? Or does antimony and potassium tartrate itself decompose, rendering it advisable to prepare a fresh solution for each day's use?

H L BURKE, M D, Lassa, Nigeria, West Africa

ANSWER—1 No

2 No. It may help in the preservation of the solution.

USE OF TRYPARSAMIDE

To the Editor—Have you any information regarding the subcutaneous administration of tryparsamide? It cannot be given to the patient intravenously and I am afraid of unpleasant tissue reactions. The manufacturers apparently have no data as to its administration subcutaneously. Do you think I can safely give it? Please omit name.

M D, New York

ANSWER—Authorities do not advise using tryparsamide subcutaneously, nor is it well tolerated by intramuscular injection. This route of administration was tried at first in using this drug, but it was found to be somewhat irritating and if used in the usual concentration, that is, 3 Gm in 10 cc, sloughing of tissue may result. In one case an abscess formed. When it is used in a more dilute solution 10 per cent or less, it is not irritating but the bulk of fluid becomes uncomfortably large for intramuscular use. Used intramuscularly, it is somewhat irritating but not unsafe. Its therapeutic effect is practically the same as by intravenous administration.

Council on Medical Education and Hospitals

COMING EXAMINATIONS

ALASKA Juneau, March 14 Sec, Dr Harry C DeVighe, Juneau
AMERICAN BOARD FOR OPHTHALMIC EXAMINATIONS Milwaukee, June 12 Sec, Dr William H Wilder, 122 S Michigan Blvd, Chicago
AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY The written examination will be given in cities of the United States and Canada where there is a Diplomate who may be empowered to conduct the examination, April 1. The general oral, clinical and pathological examination will be held in Milwaukee, June 13 Sec, Dr Paul Titus 1015 Highland Bldg, Pittsburgh
AMERICAN BOARD OF OTOLARYNGOLOGY Milwaukee, June 12 Sec, Dr W P Wherry, 1500 Medical Arts Bldg, Omaha
COLORADO Denver, April 4 Sec, Dr Wm Whitridge Williams, 422 State Office Bldg, Denver
CONNECTICUT Regular Hartford, March 14 15 Endorsement Hartford March 28 Sec, Dr Thomas P Murdock 147 W Main St, Meriden Homoeopathic New Haven, March 14 Sec, Dr Edwin C M Hall, 82 Grand Ave, New Haven
IDAHO Boise, April 4 Commissioner of Law Enforcement, Hon Emmitt Pfost, Boise
ILLINOIS Chicago, April 11 13 Superintendent of Registration, Mr Paul B Johnson, Springfield
MAINE Portland, March 14 15 Sec, Dr Adam P Leighton, Jr, 192 State St, Portland

Mississippi Reciprocity Report

Dr Felix J Underwood, secretary, Mississippi State Board of Health, reports 9 physicians licensed by reciprocity with other states at a meeting held in Jackson, Dec 12, 1932. The following colleges were represented:

College	LICENSED BY RECIPROCITY	Year Grad	Reciprocity with
Howard University College of Medicine	(1931)		Georgia
Emory University School of Medicine	(1928)		Georgia
University of Louisville School of Medicine	(1928)		Kentucky
Tulane Univ of Louisiana School of Med	(1925), (1931, 2)		Louisiana
(1931) Tennessee			
Meharry Medical College	(1931)		Tennessee
University of Tennessee College of Medicine	(1931)		Tennessee

Tennessee March Examination

Dr Alfred B DeLoach, secretary, Tennessee State Board of Medical Examiners, reports the written examination held in Memphis, March 23-24, 1932. The examination covered 8 subjects and included 64 questions. An average of 75 per cent was required to pass. Thirty-two candidates were examined, all of whom passed. The following colleges were represented:

College	PASSED	Year Grad	Number Passed
University of Tennessee College of Medicine	(1932 31)		31
Baylor University College of Medicine	(1930)		1

Puerto Rico September Examination

Dr O Costa Mandry, secretary, Board of Medical Examiners of Puerto Rico, reports the written and practical examination held in San Juan, Sept 6, 1932. The examination covered 19 subjects and included 90 questions. An average of 75 per cent was required to pass. Eight candidates were examined, all of whom passed. The following colleges were represented:

College	PASSED	Year Grad	Per Cent
George Washington University School of Medicine	(1932)	82 7	83 1
University of Louisville School of Medicine	(1931)	77 2	
Harvard University Medical School	(1932)	82 3

Book Notices

Practical Obstetrics for Students and Practitioners. By P Brooke Bland M.D. Professor of Obstetrics Jefferson Medical College Philadelphia. Assisted by Thaddeus L. Montgomery M.D. Associate in Obstetrics Jefferson Medical College Philadelphia. Cloth. Price \$8. Pp 730 with 516 illustrations. Philadelphia F. A. Davis Company 1932.

When the books written by Williams and DeLee cease to be revised, Bland's book will undoubtedly rank among the leaders, for it is worth while. It was "compiled with the object of having it fill an important place between the *large* work and the *small* manual" (author's italics) but the book contains 730 pages. The arrangement of the book is similar to that of other textbooks on the subject. The authors have included all the new contributions to obstetrics, such as the improved hormone tests for pregnancy and obstetric physiology. It is unfortunate that mention is made of veratrum viride in the treatment of eclampsia, because this is a dangerous drug, which has fallen into almost complete desuetude. Another dangerous procedure which the authors not only describe but illustrate is Schultze's (swinging) method of artificial respiration of the new-born. This procedure was long ago condemned by leading obstetricians. The illustration on page 435 of a case of dystocia, dystrophia syndrome is far from typical of this condition. For the surgical induction of labor, the insertion of a bougie is preferred. No mention is made of rupture of the membranes, a method one time severely condemned but recently used successfully and praised at such conservative clinics as the Johns Hopkins. The authors are not yet convinced of the superiority of the cervical cesarean section for clean cases as well as for those grouped as suspicious but they add, "we may come to adopt the latter (cervical) operation as the preferential plan in nearly all instances." In spite of the few defects, the book is well written and beautifully illustrated, though the reproductions of most of the roentgenograms are poor. The chapter on obstetric jurisprudence is well worth reading.

Facial Growth in Children With Special Reference to Dentition. Part I by Corliss Smyth. Part II by Matthew Young. Medical Research Council Special Report Series No 171. Paper. Price is 6d. Pp 83 with illustrations. London His Majesty's Stationery Office 1932.

"The data on which this report is based are the records of measurements of about twenty characters of the face in a series of approximately 1,400 school children 600 boys and 600 girls at ages of 8 to 14 years having normal occlusions, also 100 boys at the ages of 9 and 10 years from the same school taken at random and finally a group of 100 children from 2 to 5 years of age taken from the Welfare Clinic. The many tables of data and the standards derived from them are offered as a basis for the study of abnormal development of the face and jaws. Of the many graphs prepared six examples have been reproduced to illustrate the type of growth exhibited by the selected characters as the age increases from 8 to 14 years. The figures for the mean measurements of the length of the dental arch at the successive ages supply ample confirmation of the conclusion reached by John Hunter, Tomes and Boll that after complete eruption of the milk teeth the alveolar arch of the human jaw primarily occupied by them does not increase in length. For the purposes of comparison the data are of value only to those equipped with the same types of instruments and used to measure the characters of the face selected by the authors. Facial growth is a complicated phenomenon which at present is being studied critically by other investigators. Not only is this true but methods and material are receiving just as critical consideration. From this point

of view one may question the ultimate or even the present value of these data except to the individuals or groups intensively engaged in this type of research.

Classic Descriptions of Disease With Biographical Sketches of the Authors. By Ralph H. Major. Professor of Medicine University of Kansas School of Medicine. Cloth. Price \$4.50. Pp 630 with 127 illustrations. Springfield Ill. & Baltimore Charles C. Thomas, 1932.

The nucleus of these "classic descriptions of disease" were collected by Dr. Major "because of personal interest in the subject and partly for use in teaching." The appearance of Long's Readings in Pathology and Fulton's Selected Readings in the History of Physiology suggested the expansion of the "descriptions" until they eventually reached the present form. The selections for the most part are restricted to the field of clinical medicine (exclusive of the neurologic field) and under the headings of infectious diseases, diseases of metabolism, lead poisoning, diseases of the circulatory system, diseases of the blood, kidney diseases, respiratory diseases, deficiency diseases, allergic diseases, and diseases of the digestive tract. As the title states, there are biographic sketches of the authors. Dr. Major has taken great pains to compile a truly representative selection of quotations from the world's leading medical benefactors by intensive work of his own and by acquiring a considerable amount of expert advice and criticism. A commendable achievement is the result. This book should be accessible to every real physician for perusal during such loose moments as he can spare from practice. The publisher is to be commended again for his probable financial sacrifices in fostering the cultural side of medicine. The present volume as well as the volumes by Long and Fulton would make ideal and treasured gifts for any medical man.

Intracranial Pyogenic Disease. A Pathological and Clinical Study of the Pathways of Infection from the Face, the Nasal and Paranasal Air Cavities. By A. Logan Turner M.D. LL.D. FRSE Consulting Surgeon Ear and Throat Department Royal Infirmary of Edinburgh and F. Esmond Reynolds M.D. D.T.M. & H. M.R.C.P. Superintendent of the Laboratory of the Scottish Asylums Pathological Scheme. Cloth. Price 12/6. Pp 271 with 82 illustrations. Edinburgh Oliver & Boyd, 1931.

The studies which form the main excuse for this book have involved a stupendous amount of work in cutting serial sections, gross and microscopic, of many brains, together with the contiguous skull and soft tissues. It was the hope of the authors that in this manner they might add to our knowledge of the manner in which intracranial pyogenic diseases arise. The microscopic details and case reports, which are presented in tiresome and excessive detail, make up the bulk of the presentation. Nor is it possible to believe that anything of material value has been added by the microscopic investigations. From clinical and gross pathologic studies it is well known that pyogenic infections of the brain arise either by direct extension of contiguous infections or through the blood vessels, whether venous or arterial. As a matter of fact, the pathways of infections into the brain from venous sinuses or contiguous tissues are much better and more safely determined by gross than by microscopic studies. By the latter the perspective is all too frequently lost. The diagnostic features of sinus thrombosis and cerebral infections are well presented and in much more readable form, but even here nothing new has been added. There seems to be little reason for presenting investigations of this character in book form.

The Physiology of Large Reptiles With Special Reference to the Heat Production of Snakes, Tortoises, Lizards and Alligators. By Francis G. Benedict. Director Nutrition Laboratory, Carnegie Institution of Washington (Carnegie Institution of Washington Publication No 425). Paper. Pp 539 with 106 illustrations. Washington D.C. Carnegie Institution of Washington 1932.

After an account of the methods of study and the results obtained there follows a discussion of a "comparison of metabolism of cold-blooded animals with that of warm-blooded animals, cell temperature of which has been lowered below 37° to approximately that of cold-blooded animals" (p. 417). The monograph concludes with this statement: "If our research serves no more than to point out to students in comparative physiology some of the intermediary phases that may occur between the lowest of the cold-blooded organisms and the highest of the warm-blooded organisms (man) it has been worth while. The results of this painstaking and at times dangerous research can be said to be of use or interest only to special (laboratory) students of metabolism."

Lehrbuch der Mund und Rachenkrankheiten Herausgegeben von Josef Berberich. Paper. Price 53 marks. Pp 587, with 213 illustrations. Leipzig: Georg Thieme, 1932.

This volume covers the field of the diseases of the mouth and throat, including tumors but excluding those produced by injury. It is the joint product of fourteen authors, a division of labor that enhances the value of the work but which introduces some variation in the form and arrangement of the subject matter. There is an adequate index and each section is followed by a limited list of references to the literature. The illustrations are well chosen and clearly reproduced on good paper. The sections on the manifestations of systemic diseases in the mouth and throat and the mouth lesions of skin disorders are unusually complete and cover fields that, as a rule, receive but scant attention in the American textbooks on diseases of the mouth. The chapter on the bacteriology of the mouth is conspicuous because of the absence of names such as *B. acidophilus* and because of the presence of others relatively unfamiliar in the English literature. On the other hand, it includes a well written discussion of the mouth as a focus of infection. Occasional statements are encountered that are not in harmony with the best modern practice, such as (page 321) "Therapy of fibrous epulis consists in radical excision including the base, and as rule including the tooth adjacent thereto." Of course, it is rarely necessary to extract the tooth in the treatment of this form of epulis. This book is a valuable addition to the literature on mouth diseases and, together with the Sonntag-Rosenthal textbook on surgical conditions of the mouth and jaws, covers the whole range of this field in an adequate and scholarly manner.

Outline of Preventive Medicine for Medicinal Practitioners and Students Prepared under the Auspices of the Committee on Public Health Relations, New York Academy of Medicine. By 24 Contributors. Editorial Committee: Frederic E. Sondern, Chas. Gordon Heyd and E. H. L. Corwin. Second edition. Fabrikoid. Price, \$5. Pp 462. New York: Paul B. Hoeber, Inc. 1932.

The appearance of a book about preventive medicine ought not to be noteworthy because the volume happens to be written by physicians, yet that is exactly the situation. There have been books in plenty about preventive medicine, written by every variety of doctor except doctors of medicine. This volume is the work of twenty-four contributors whose names are well known to the medical profession, and its sponsorship by the academy of medicine in our largest metropolitan center is significant of the trend of the times. Preventive medicine is coming back home where it belongs, in the hands of the medical profession. In this edition new chapters have been added, dealing with the private physician and the health authorities, the dentist and oral hygiene, and preclinical medicine and hygiene—all significant topics. These chapters add a great deal to the usefulness of the volume. For the practitioner, the health officer, the public health nurse and the social worker, the volume is an excellent guide to preventive medicine in its broadest aspects. It is not suitable, however, for placing in the hands of enlightened lay persons, unless they may happen to be engaged in scientific pursuits. It is not written for the comprehension of the lay person with education centered in liberal arts and with only the vaguest notions of science. The book is broad in scope, concise in treatment, authoritative, conveniently arranged, and easy to read. It is well indexed. The format is attractive. If it has the wide distribution it merits, it should exert a beneficial influence on the public health through the medical profession.

Les abcès du poulmon Par Michel Léon-Klindberg, médecin des Hôpitaux de Paris et Robert Monod, chirurgien des Hôpitaux de Paris. Avec la collaboration d'A. Soulas, assistant d'oto-rhino-laryngologie à l'Hôpital Laennec. Paper. Price 55 francs. Pp 322, with 119 illustrations. Paris: Masson & Co. 1932.

This well illustrated monograph deals with the history, pathologic anatomy, etiology, clinical forms, complications, diagnosis and various types of treatment of pulmonary abscess. The illustrations include drawings and numerous reproductions of photomicrographs and roentgenograms—the latter with and without contrast medium drawing and illustrations of operative procedures and photographs of patients. Sixteen case reports, a recent bibliography and an index are appended. The authors state that their opinions and conclusions are based chiefly on their personal experience with 150 cases during a period of

more than ten years, but their topical discussions include numerous citations and discussions of authoritative contributions to the world's literature. The introduction contains some interesting observations on the increased incidence of pulmonary abscess. All forms of treatment, medical and surgical, are discussed rather impartially, but the authors set forth their own views in a concluding chapter. The monograph is a notable contribution to the subject of pulmonary abscess.

Manual of Clinical and Laboratory Technique By Hiram B. Wells, A.B., M.D., F.A.C.P. Associate Professor of Medicine, College of Medicine, University of Cincinnati and Raphael Isaacs, A.M., M.D., F.A.C.P., Associate Professor of Medicine, Assistant Director of the Thomas Henry Simpson Memorial Institute for Medical Research, University of Michigan. Ann Arbor. Fourth edition. Cloth. Price \$1.50. Pp 117, with one illustration. Philadelphia & London: W. B. Saunders Company, 1932.

The data in this manual were compiled with the idea that the book might be used as a clinical and laboratory guide. The work in the present edition has been entirely revised and new facts have been added. A convenient addition is a complete table on the nutritive value of foods. The book is a condensed yet comprehensive presentation of clinical and laboratory data of particular interest to the student or intern. Enough essential facts are presented to make it practical, and it will serve as a workable aid in the systematic study of the individual patient.

History of the Royal Hungarian Francis Joseph University of Sciences, Founded at Kolozsvár in 1872 and Reopened at Szeged in 1921 Published on the Occasion of the Fifteenth Anniversary of the Foundation of the University, Szeged, June 20, 1922. Paper. Pp 20, with illustrations. Budapest: Franklin Society Press [n.d.]

The occasion of writing this brochure was the formal opening, amid due solemnities, of the university at Szeged, Oct. 9, 1921. Seven full page illustrations accompany the text. The early history of university instruction or attempts in that direction in Transylvania are recounted from 1541 on. Religious and political difficulties interfered with the natural evolution of this school of higher learning. Its vicissitudes are noted chronologically. May the development of the institution be more peaceful in the future.

A Textbook of Biochemistry for Students of Medicine and Science By A. T. Cameron, M.A., D.Sc., F.I.C., Professor of Biochemistry, Faculty of Medicine, University of Manitoba. Third edition. Cloth. Price \$4. Pp 548, with 15 illustrations. New York: Macmillan Company, 1931.

The third edition of this comprehensive textbook, like the earlier editions, is a good presentation of the more important biochemical contributions bearing on medical science. It is thoroughly revised and somewhat enlarged by the addition of new material to previous chapters and the inclusion of new chapters on internal secretions, muscular activity, and tissue respiration. The additions are well presented, if one considers the great mass of material covered in the discussion. It would seem desirable to present more critical chemical information on the chemistry of the carbohydrates, lipins and proteins and their behavior toward reagents than the rather limited treatment found in this otherwise admirable work.

Die konservative Behandlung entzündlicher Genitalerkrankungen der Frau Von Priv.-Doz. Dr. Gustav Döderlein, Oberarzt der Universitäts-Frauenklinik der Charité, Berlin. Therapie in Einzeldarstellungen. Wissenschaftliche Grundlagen und praktische Anwendung. Herausgegeben von Prof. Dr. R. von den Velden und Priv.-Doz. Dr. P. Wolff. Boards. Price 6.50 marks. Pp 117, with 7 illustrations. Leipzig: Georg Thieme, 1932.

Döderlein, who is associated with the gynecologic clinic of the Berlin Charité, presents a monographic review of genital inflammations. The monograph is divided into three parts. In the first part the author discusses etiology, pathogenesis and diagnosis of genital infections. In the diagnosis of gonorrhea he mentions the vulnerability of the vagina of the child, of the pregnant woman and of the senile woman. The sedimentation test (Linzemeier technique) is stressed as an important procedure in the diagnosis and prognosis of inflammatory adnexal disease. The second part of the book deals with the management of the nonspecific genital inflammations; there is a scholarly differential diagnosis of pruritus vulvae including detailed description of such unusual conditions as *ulcus vulvae acutum* and *ulcus vulvae chronicum* (esthiomene). The author gives only passing mention to *trichomonas vaginitis* and maintains the opinion that the parasite is nonpathogenic. However,

in the presence of trichomonas, he advises treatment with silver nitrate and boroglycerin. The third part of the treatise deals with the special management of gonorrhea and tuberculosis of the genitals. The conservative treatment of gonorrhea is stressed. The difficulty and at times impossibility of diagnosing genital tuberculosis is emphasized. In from 80 to 90 per cent of cases of genital tuberculosis the tubes are involved, and in half of these there is an associated tuberculous endometritis. The author advocates roentgen treatment for genital tuberculosis, regardless of surgery. Less than a sterilizing dose is advocated on the basis that a slight destruction of the tuberculous granulations causes absorption and stimulation of immunity. Castration doses of x-rays are advocated only in cases associated with marked menorrhagia. The treatise is an excellent one, particularly for the specialist in gynecology.

Oral Spirochetes and Related Organisms in Fusio Spirochetal Disease
By David T. Smith, A.B. M.D. Associate Professor of Medicine, Duke University School of Medicine, Durham, N. C. Cloth, Price \$4.50. Pp. 243 with 53 illustrations. Baltimore: Williams & Wilkins Company, 1932.

This excellent volume can be recommended unreservedly to all practicing physicians. It is the first complete and authoritative review of the subject. It presents a concise systematic discussion of fusospirochetal infection in every part of the body covered by reports in the literature, as well as a summary of its occurrence in animals. The length and extent of the author's experience give great authority to his careful conclusions and advice. The general summary on the dust cover represents the clinical conclusions of the volume. Fusospirochetal disease is preventable, its diagnosis is easily established, and its treatment is fundamentally the same in all the various types of lesions. The closely woven story of history, experimental data, reproduction in animals, clinical picture and treatment is of rare value to the clinician. The physical make-up of the book is most creditable and the number of typographic errors is minimal for a first edition. Some of these should not have crept in. For example, in the bibliography in reference 261 "Jour Cun Invest" appears instead of "Jour Clin Invest". On page 69, figure XVI shows an "amebic cyst" in material from pyorrhea, and elsewhere *Endamoeba gingivalis*, which does not produce cysts, is misnamed *E. gingivitis*. The author refers to tartar emetic as a dangerous drug for intravenous use. While this is true, with a simple and accurate technique it is probably no more dangerous than neocarsphenamine and emetine, if as much so. In general, the illustrations would be greatly improved by using photomicrographs largely. Many of the drawings are below par. The bibliography of 822 titles is not the least valuable feature of the book. The author presents a good argument for interchangeability between the fusiform and the spirilliform organisms. In general the volume can be accepted as an important addition to the library of clinical and experimental medicine.

Le doilechocolon. Clinique, radiologie, thérapeutique. Par M. Chlray, professeur agrégé à la Faculté de médecine de Paris. A. Lomon, électro-radiologiste des hôpitaux et R. Wahl, chef de clinique à la Faculté. Paris: Pp. 209 with 44 illustrations. Paris: Masson & Cie, 1931.

This is a clinical and roentgenographic study of the redundant and enlarged colon. The etiology, pathology, symptoms and clinical manifestations are discussed, also the radiologic considerations and finally the treatment. Numerous cases are cited and the management both medical and surgical, is given. The bibliography is complete. The illustrations are clear.

Physiology and Anatomy. By Esther M. Greisheimer, B.S. In Education. A.V. H.D. Associate Professor of Physiology, the University of Illinois at Urbana-Champaign. Cloth, Price \$3. Pp. 601 with 355 illustrations. Philadelphia: London & Montreal: J.B. Lippincott Company, 1932.

This is intended as a textbook for nurses. It deals with gross and minute structure and physiology. It includes also something of embryology and rather extensive paragraphs on clinical applications. The book is well fitted for this group of student. The style is simple, the sentences are short and the arrangement is almost a tabulation. The statements are of course dogmatic and do not raise in the mind of students any question or wonder as to the nature of the processes said to occur. The paragraphs in each topic are of necessity greatly condensed. Occasionally, as in the paragraph on the spleen, the consideration is extreme. Illustrations, diagrams and tabulations help the student to apprehend the ideas presented. The

illustrations are well devised and well reproduced. A glossary at the end should be of great value to such student nurses as are not provided with dictionaries. Dr. Greisheimer has undertaken a difficult task and has produced a book well adapted to the needs of nurses. They will find it an excellent textbook. With its help they can get elementary ideas of anatomy and physiology and enough of the terminology to understand the general character of the patient's disease and the physician's comments and instructions.

Die Dickdarmschleimhaut ihre normale und pathologische Funktion im Röntgenbilde. Von Priv. Doz. Dr. Werner Knothe, Leiter der Röntgenabteilung der II. medizinischen Universitätsklinik der Charité, Berlin. Boards, Price 8 marks. Pp. 56 with 113 illustrations. Leipzig: Georg Thieme, 1932.

This is a comprehensive study of the large intestine, focusing attention on changes of its lining in health and disease. The illustrations are excellent and numerous. It was written as a result of the writer's association with H. H. Berg in the x-ray division of the von Bergmann clinic in Frankfurt-on-Main. By the use of thin, opaque mediums the beautiful fluoroscopic pictures of normal mucosa and mucosa under pathologic conditions are portrayed. The roentgenographic work was repeatedly checked by anatomic specimens when it was possible to obtain them. There is a rich bibliography at the end. This monograph is recommended for any one interested in radiography.

Fun in Bed. The Convalescent's Handbook. Edited by Frank Scully and an All Star Cast including Eddie Cantor, Frank Sullivan, Peter Arno, Robert Ripley, Ring Lardner, O. Soglow, Harry Hereshfield, Patricia Collinge, Leonard Dove, Ogden Nash, Arthur Kober, Sidney Lenz, George Jean Nathan, William Shakespeare, etc. With a preface by Logan Clendening. Cloth, Price \$2.50. Pp. 187 with illustrations. New York: Simon & Schuster, 1932.

The compiler of this work has been for years an invalid. He therefore feels that he knows what will amuse most invalids when they are sick in bed. The collection includes books, funny pictures, crossword puzzles, anagrams, humorous essays, dramas, and a humorous preface by Logan Clendening. The book is sure to be amusing to any one, invalid or otherwise, because it is a collection of material from sure-fire sources.

Theoretische und klinische Pharmakologie. Ein Lehrbuch für Studierende und Ärzte. Von H. v. Hoesslin, Prof. Dr. med. und Franz Müller, a. o. Prof. Dr. rer. nat. et med. Fourth edition. Cloth, Price 10.20 marks. Pp. 245. Leipzig: Georg Thieme, 1933.

The object of this book is to unify theoretical and practical pharmacology, especially for the benefit of the practitioner. While the book is small, it includes most drugs discussed in the larger textbooks. Consequently a discussion of theories of action is minimized. In the theory of narcosis, for example, practically only the Meyer-Overson theory is discussed. In place of theory the authors have emphasized the practical to the extent of including many illustrations of how to give the drugs in prescriptions. The subject matter is well arranged, accurate and reliable, but the discussions are necessarily brief—too brief for either a textbook or a reference work. It is recommended to those who desire to know how the subject is viewed by the German practitioner and to those who may wish a brief reliable textbook in that language.

The Gold Headed Cane. By William Macmichael, M.D. Edited with Explanatory and Illustrative Notes and an Essay on William Macmichael, M.D. His Life, His Works and His Editors. By Herbert Spencer Robinson. Containing the Original Illustrations of the 1828 Edition and Hitherto Unpublished Portraits of the Macmichael Family and a Reproduction of William Macmichael's Handwriting. Cloth, Price \$3.50. Pp. 223 with illustrations. New York: Froben Press, Inc., 1932.

This volume is a reprint of previous editions of this medical classic. For those who may not remember, the gold-headed cane was passed down through the hands of several famous British physicians. In his imaginative account, the author provides the life and history of these men.

Die Krankheiten der Verdauungsorgane. Diagnostik und Therapie. Von Dr. Walter Wolff, Chefarzt der Inneren Abteilung am Königin Elisabeth Hospital zu Berlin-Oberschöneweide. Paper, Price 10.50 marks. Pp. 261 with 33 illustrations. Berlin: Urban & Schwarzenberg, 1932.

This book deals rather superficially in most instances with diseases of organs of the digestive tract and adds little to what is already in print on the subject.

Medicolegal

Alleged Malpractice in Performing Cataract Operation

(*McLeod v Hichs* (N C) 164 S E 617)

The plaintiff sued the defendant-physician for damages for alleged negligence in removing a cataract. The plaintiff claimed that the defendant negligently made an incision into the white part of his eye, which penetrated the posterior chamber, caused the loss of the vitreous humor and necessitated the removal of the eye about three years later. The defendant, on the other hand, claimed that the incision was properly made at the corneoscleral junction and that when the cataract was removed it was discovered that the eye was practically destroyed by disease and that the vitreous humor had greatly deteriorated. At the conclusion of the evidence the trial judge directed a verdict for the physician, and the patient appealed to the Supreme Court of North Carolina.

The first question to be determined, said the Supreme Court, is whether or not an incision was made into the white of the eye. The plaintiff and several other laymen testifying on his behalf stated that there was such an incision. Medical experts who examined the eye testified that there was no such incision, but that there was an incision at the corneoscleral junction. The determination of the location of the incision is not exclusively a technical question, and lay testimony is competent in regard to it. The testimony of a layman with respect to the location of a knife incision or wound on the exterior of a body is entitled to the same weight as that of an expert witness. Therefore, said the court, in passing on the judgment of non-suit, it will be assumed that there was a cut or incision in the white portion of the eye. In the final analysis the plaintiff sued to recover damages for the loss of his eye. The evidence indicates but three possible causes. First, that the eye was destroyed by disease, in which event, in the absence of evidence that the operation accelerated the course of natural causes, the defendant is not liable in damages. Second, that the operation performed by making an incision at the corneoscleral junction and removing the cataract was negligently done, but all the testimony is to the effect that the cataract was removed in the exercise of that technic and skill required by law. Third, that the cut in the white portion of the eye was the proximate cause of the injury. But, said the court, even if we assume that the incision was negligently made, there is no evidence that it caused the loss of the eye, and without such evidence the plaintiff is not entitled to recover. The judgment in favor of the physician was accordingly affirmed.

Optometry, Revival of Revoked License—The Maryland Code of Public General Laws, 1924, article 43, section 321, requires every registered optometrist to pay an annual registration fee and authorizes the revocation of the license of an optometrist who fails to pay it, but it is silent as to the reinstatement of a license so revoked. Section 323 authorizes the revocation of licenses because of various forms of unprofessional conduct and provides for the reinstatement of revoked licenses, but reinstatement is conditional on the licentiate's showing to the satisfaction of the licensing board, on examination, that he is fully qualified to practice. Kahn, a licensed optometrist, failed to pay the annual registration fee required by law. The state board of examiners of optometry therefore, in December, 1925, revoked his license. In 1927, Kahn asked the board to reinstate his license, offering to pay the annual fees for the period during which the license had been revoked. The board refused to accede to his request, however, unless he passed a satisfactory examination. He thereupon petitioned the Baltimore city court for mandamus to compel the board to reinstate his license, without examination. The court dismissed his petition and he appealed to Court of Appeals of Maryland. The section of the law, said the appellate court under which the board revoked Kahn's license is purely a taxing measure. It has no reference to the qualifications of the applicant. This section needs no further provision to enable a licentiate whose registration has been revoked for failure to pay the required

fee to procure the reinstatement of his registration on paying the tax for the current year. It would be unreasonable to suppose, said the appellate court, that the legislature meant that a licentiate desiring to suspend practice for a year or two could not resume practice on paying the fixed license fee, except at the discretion of the board. The order of the court below dismissing Kahn's petition for mandamus to compel the board to reissue his license was reversed and the case remanded—*Kahn v State Board of Examiners of Optometry* (Md), 161 A 12.

Workmen's Compensation Acts Liability of Physician for Malpractice—The plaintiff was injured in the course of his employment. Under the provisions of the Georgia workmen's compensation act, his employer's insurer employed the physicians who treated him. The patient sued these physicians and others, claiming that he had been injured by the insurer's failure to furnish proper medical attention and by the neglect of the physicians in giving proper care. The physicians and other defendants demurred, contending that any consequences of malpractice by the physician-defendants were a part of the injuries resulting from the accident and compensable as such. The workmen's compensation act of Georgia (Georgia Laws 1920, pp 167-182, section 27) provides that an employer shall not be liable for malpractice by a physician furnished by him pursuant to the provisions of the act, "but the consequences of any such malpractice shall be deemed part of the injury resulting from the accident and shall be compensated as such." A judgment was entered dismissing the suit, which judgment the court of appeals of Georgia, division 1, affirmed. All the parties, said the court, were operating under the workmen's compensation act, and the defendant physicians were treating the petitioner by virtue of that act—*McConnell v Hamcs* (Ga), 164 S E 476.

Malpractice Liability of Dental Corporation—United Dentists, Inc., was a corporation organized under the laws of Virginia and "authorized to engage in the practice of dentistry in all of its branches." The plaintiff consulted an employee of the corporation at its office in Norfolk, Va. He advised that a certain tooth be extracted and with her consent extracted it after injecting a solution of procaine into the gum. Infection followed at the point of injection. She sued the defendant corporation, charging negligence of the corporation's agent, based on his failure properly to sterilize the gum and his hypodermic needle. Judgment was given against the corporation, which was affirmed by the Supreme Court of Appeals of Virginia—*United Dentists, Inc., v Bryan* (Va), 164 S E 554.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

American Journal of Clinical Pathology, Baltimore

2 437-494 (Nov.) 1932

- Some Essentials for Satisfactory Work in Allergy J H Black, Dallas, Texas—p 437
Myeloid Immaturity in Pernicious Anemia F J Heck Rochester Minn—p 443
*Hematopoietic System and Infection B Markowitz Bloomington, Ill—p 449
Gelatinous Carcinoma of Breast. N Enzer, Milwaukee.—p 457
*Colloidal Benzoin Test of Cerebrospinal Fluid Its Clinical Value N Evans and W R. Dodson Los Angeles—p 463

Hematopoietic System and Infection—Markowitz states that there is a constant physiologic balance between the production and destruction of blood cells, this process maintains an equilibrium which is compatible with health. The introduction of a foreign substance as, for instance, infection stimulates the formative tissue to greater production of blood cells, this may be called the normal producing capacity. Some abnormal body constituent may account for the lack of proper activation of these formative tissues, which results in some form of blood dyscrasia. In the leukemias there is a hyper-producing capacity with overproduction of cells, whereas in agranulocytosis there is a hypoproducing capacity with a lack of cells. The histopathology of all leukemias indicates that there is no essential difference between the acute, chronic and aleukemic forms. Many septic processes seem to produce the same clinical symptoms and histologic changes that are seen in diseases of the hematopoietic system. Aplastic anemia, agranulocytosis and mononucleosis are usually associated with septic processes, while Hodgkin's disease presents histologic evidence of inflammation.

Colloidal Benzoin Test of Cerebrospinal Fluid.—In a review of the literature, Evans and Dodson found evidence that indicates that of the colloidal tests used in examination of the spinal fluid the benzoin test is the simplest to prepare and read, is as sensitive as and more informative than the gum mastic test, and is more sensitive than and as informative as the colloidal gold test. Their study of the data obtained from 2009 colloidal benzoin tests on cerebrospinal fluids from 1,800 patients signified that (1) the benzoin test is not a specific test in the same sense as the Wassermann reaction, (2) it is of value in differentiating active dementia paralytica from other forms of neurosyphilis (3) it is probably of value in differentiating epidemic encephalitis from poliomyelitis and tuberculous meningitis, and (4) a high percentage of positive readings is obtained in disease of the central nervous system but a positive second zone reading is occasionally obtained in certain conditions not associated with organic disease of the central nervous system.

Cancer of Vulva in Young Women. H Strauss Brooklyn—p 760

Reconstruction of Oviducts—Holden and Sovak report that seven of the ten patients operated on, or 70 per cent, have patent tubes after operation. The corrected percentage of patency after operation is 77.7 per cent. The authors reconstructed oviducts having occlusions in the outer third by performing what they have termed a "circumcision" operation as suggested by Bonney, everting the tube by bringing back the mucosa to the serosa for a distance of from 1.5 to 2.5 cm, thereby eliminating raw surfaces at the newly constructed ostium and avoiding adhesions and occlusions, which are so prone to follow plastic operations. For the reconstruction of oviducts showing occlusions in the inner two thirds they used the implantation operation which is as follows. The site of the occlusion is noted by air insufflation and the tube is severed proximal to the occluded area until a free passage of the insufflated air is evident. The uterine portion of the occluded tube is freed as far as the cornu from its attachment to the broad ligament, the cutting being done as close as possible to the tube, to avoid impairment of the ovarian circulation. Bleeding vessels of the broad ligament are clamped and tied with number 00 plain gut. The uterus is firmly held while the tube and its intramural portion are reamed out by a circular movement of the instrument entering the uterine cavity and maintaining as nearly as possible the normal position and course of the tube. The old occluded stump of the tube and the chronically infected cornual tissue are readily removed when the reamer is withdrawn. The new opening into the uterus will have a diameter of approximately 0.5 cm. The patent portion of the tube is also freed from its broad ligament attachment for a distance of about 0.5 cm, bleeding controlled, and then bisected longitudinally by cuticle scissors guided by a probe inserted within its lumen. Through the superior and inferior ends of the bisected tube a long number 00 chromic suture is passed and the ends of the suture clamped for sur-

ther use A Reverdin needle is inserted about 1 cm beyond the center of the fundus, posteriorly, and passed out through the newly created uterine opening, and the ends of the suture previously applied to the superior bisected portion of the tube are reinserted into the eye of the needle, the needle is withdrawn, and the sutures are brought out on the posterior surface of the uterus without tension. The same procedure is repeated by passing the Reverdin needle through the anterior surface of the fundus and bringing out the suture on the inferior portion of the bisected tube. The serosal covering of the bisected portion is traumatized, and by gentle pulling of the anterior and posterior fundal sutures the tube is gradually drawn into the newly created opening and its ends into the uterine cavity. The sutures are anchored on the fundus and two or three fine supporting sutures are passed through the serosa of both the tube and the uterus. The patency of the newly implanted tube is again tested by the use of the insufflation syringe. The reimplanted tube and ovary are suspended by the Poole technic and the uterus by a one point suspension.

Uterotubal Insufflation—According to Rubin's studies on the normal human tubes and the oviducts of the sow, the diagnosis of nonpalpable tubal adhesions and tubal stenosis can be made by uterotubal insufflation with the aid of the kymograph. It is based on the fact that tubal contractions in the presence of these lesions are completely absent or markedly changed. Observations were made at laparotomy, where these lesions were found affording an opportunity of checking the insufflation observations. Characteristic curves were produced. In the presence of tubal stenosis the initial rise of pressure was as a rule well above 100 mm of mercury. Instead of dropping sharply and exhibiting oscillations, the curve produced was rounded and the descent gradual. Fluctuations were absent. In the presence of peritubal adhesions without constriction of the lumen, the pressure was less elevated. The contractions were infrequent, irregular or shallow and at times entirely absent, depending on the degree of immobilization produced. The location of pain elicited during the performance of the test and the auscultation observations were found to vary with the site of obstruction. Roentgenologic examination of the tubes after the injection of iodized poppy-seed oil proved of less value than laparotomy in checking the insufflation observations of peritubal adhesions and tubal stenosis. The disadvantages of the oil in this respect were due to its rapid escape from the cervix in some cases, its inability to pass high grade strictures in most cases, and its tendency in the strictured tubes to produce foreign body reactions. Insufflation of the excised but surviving uterus and tubes reproduced curves similar to those found by clinical uterotubal insufflation when adhesions and strictures were present. By the artificial reproduction of immobilizations and stenosis of the tubes, the paralyzing effect on rhythmic tubal contractions and tubal peristalsis was also demonstrated.

Influence of Age and Race on Duration of Labor—Peckham made an analysis of the effect of age and race on the duration of labor in a series of 13,658 consecutive deliveries at or near term. From his study he concludes that Negro women, both primiparas and multiparas, and regardless of age, have consistently longer labors than white women. In both races, a consideration of total cases reveals an increased duration of labor in the older age groups, which, however, is more marked among Negro women than white women. Omitting cases of contracted pelvis, this age increase persists in the Negro race but almost disappears in the white race. Considering only those cases delivering spontaneously, the duration of labor tends to fall with advancing age in white patients, even primiparas, although it increases in Negro women regardless of parity.

Treatment of Dyspareunia—Mayer states that dyspareunia varies as to the cause, as to the individual and as to the domestic situation. The causes may be organic, psychogenic or a combination of the organic and the psychogenic. In the diagnosis, in addition to the ordinary gynecologic history it is essential to determine the familial setting, the developmental history, other complaints and other experiences in the past. Among the most important of the facts in the present history are the severity, the duration, the onset, the patient's attitude toward the complaint and to her mate, the previous attempts at treatment, the frequency, duration and position of coitus, and

the presence or absence of orgasm. Treatment depends on the type of dyspareunia and its cause. It may be prophylactic by premarital instruction or actual. The actual treatment should be radical. If the cause is mental, the treatment should be mental, though it must be understood that this does not preclude local measures and that the patient may well attribute a cure to these local measures. The treatment of psychogenic dyspareunia commands extended attention. It is important for the gynecologist to differentiate those cases in which he can reasonably expect to get a good result from the suggestive measures at his disposal and those which he had better refer to a psychotherapist. The majority of cases of dyspareunia coming to the gynecologist are primarily psychogenic, although all the cases have some psychologic factors. The more these factors are taken into account, the more efficacious is the treatment. It is of great importance to interview the husband. Acquired dyspareunia may result from fear of pregnancy, in which one may combine a brief psychotherapy with adequate contraceptive advice. Prolonged psychotherapy offers a reasonably fair prognosis only as far as the dyspareunia is concerned, though the prognosis is poor so far as frigidity is concerned.

Peptic Ulcer—According to Smithies, peptic "ulcer," esophageal, gastric or duodenal in location, rarely begins as a mucosal lesion. The primary visceral defect and the focus from which arise recrudescences are a mural disturbance in tissue structure and specific, secretory function. Mucosal damage, which converts the mural lesion into one of ulcer type, is a complication or extension of mural damage demanding treatment, because then the mural lesion is limited in its capacity to repair by the proteolytic action of the gastric juice. "Ulcer" healing, therefore, is resolved into two distinct and definite phases: (1) epithelial reconstruction, partial, without normal, histologic, glandular structure or with such, and (2) the disappearance of the primary mural lesion. There are many local systemic or constitutional disharmonies capable of producing visceral mural changes, which may extend themselves so as to include the mucous membrane and hence convert the mural lesion into one of ulcer form. The therapy of peptic ulcer treatment calls for the eradication of the mural lesion by excision or by measures that allow the development of scar tissue and the attempt to restore mucosal epithelization. Nonsurgical management of peptic ulcer is followed by healing, sometimes permanent, in from 60 to 77 per cent of instances. Gastric mucin has been advanced as an agent that prevents mucosal proteolysis by "buffering" free hydrochloric

acid, by mechanically protecting the injured mucous membrane and by improving the systemic capacity for healing through the agency of increased nourishment. In the author's study of thirty-nine patients with peptic ulcers, he was not able fully to substantiate the claims of Fogelson, Atkinson or Brown. The treatment by Fogelson's gastric mucin was handicapped because the mucin is difficult to preserve, is obnoxious as to odor and taste, is difficult to administer, is unreliable as to dosage and effects, is expensive, and, in the group of patients observed by the author, appeared to have toxic potentialities.

Stoneless Gallbladder—On the basis of 433 gallbladder operations, of which 113 were stoneless, Stanton states that all actual objective data studied by him point to the conclusion that the one reliable indication of gallbladder disease of a type yielding to surgical intervention is the presence of well defined attacks of gallbladder colic. If the surgeon is definitely certain of his ground relative to the clinical history of biliary colic, he can proceed to remove the gallbladder irrespective of obvious pathologic changes recognizable at the operating table. Just so far as the clinical picture of true biliary colics becomes doubtful, or the clinical picture shades into ill defined digestive disturbances of the general type that many surgeons have been wont to call the symptoms of the precalculous stage of cholecystitis, do the end-results of operative treatment begin to fail. It seems highly probable that the indications for operation must be based and justified almost wholly on the symptomatology, and that little reliance can be placed on the pathologist's report until such time as pathologists learn to recognize a pathologic condition corresponding to the symptomatology.

Recurrent Prostatic Hypertrophy—From a review of the literature, Laskey concludes that prostatic adenomas recur and may produce symptoms as severe as at the time of the first operation. Recurrence may be due to nodules left at the time of the first operation or to activity in regenerative centers in the prostatic capsule. At the time of the first operation one must be extremely careful to remove the entire adenomatous prostate with nodules, and so on. He reports two cases in men aged 61 and 62. One had recurrent symptoms with obstruction within four years and had a second prostatectomy after five years; the other had symptoms with palpable enlarged recurrent adenoma within two years.

Aberrant Endometrium—Hill found in the records of Touro Infirmary 135 patients with some form of aberrant endometrium in a series of 1,200 patients operated on for some pelvic manifestation between January 1927 and January 1931. Of these 135 patients, 15 per cent had adenomyomas of the uterus and 85 per cent had peritoneal endometriomas. The aberrant endometrium in the pelvis was considered to be extensive enough to produce some of the symptoms in 26 per cent of the patients. During the time this series was taken, 497 patients were operated on for uterine fibroids, 280 for chronic salpingitis, 202 for uterine displacements and 40 for cystadenomas of the ovary. The correct diagnosis was made at the time of operation in 58 per cent of the patients of the gynecologic services and in only 2 per cent of the general surgical services. In 19 per cent the lesions were so small that they could be recognized only by the microscope. Fibroids were associated with the aberrant endometrial tissue in 46 per cent of the patients, displacements of the uterus in 8 per cent and pelvic inflammatory disease in 37 per cent. The youngest patient was 16 years old, the oldest 61. Thirty per cent of the patients were sterile. One patient was the mother of twelve children. Twenty per cent of the patients with marked endometriosis were unmarried. Menorrhagia was a symptom in 22 per cent, metrorrhagia in 11 per cent, dysmenorrhea in 26 per cent and no menstrual disturbance in 51 per cent. Three per cent were past the menopause. Dyspareunia was present in several. Aberrant endometrium was found in a normal pregnant woman and in a patient with an extra uterine pregnancy. In neither of these patients was there a decidua reaction in the aberrant endometrium. Three patients were operated on and ruptured chocolate cysts found. In none of the three was this suspected before operation. There are no constant characteristic signs or symptoms of aberrant endometrium. The most important individual symptom is pain and tenderness over the site of the growths during the menstrual period. This however is the exception and not the rule. Aberrant endometrium probably originates both from the implantation of uterine mucosa

regurgitated through the tube and from a metaplasia of the germinal epithelium or pelvic peritoneum.

Pseudomenstruation—Mazer and Ziserman state that amenorrheic and irregularly menstruating women are admittedly hypofunctioning, women who menstruate regularly and in whom there is no demonstrable cause for the existing sterility present a problem in diagnosis. In these women a premenstrual curettage and the simultaneous determination of the hormone content of the blood by the Frank and Goldberger method are invaluable from the standpoint of diagnosis and treatment. The failure to obtain a premenstrual endometrium and a mouse unit of female sex hormone a day or two before the expected flow in regularly menstruating women is indicative of ovarian dysfunction, either primary or secondary to anterior pituitary deficiency. For the following reasons the authors infer that these women do not ovulate: 1 In the human being and *Macacus rhesus*, the presence of a normal corpus luteum is invariably associated with a progesterational endometrium. 2 An interval endometrium in *Macacus rhesus*, obtained at the onset of the flow, is invariably associated with an absence of ovulation and corpus luteum. 3 In the course of abdominal operations on regularly menstruating women who were at the end of the menstrual cycle, some surgeons occasionally have found a total absence of a recent or old corpus luteum. 4 The absence of a demonstrable quantity of female sex hormone in the circulating blood a few days before the ensuing menstruation also points to a possible failure of luteinization, in view of the fact that 94 per cent of regularly menstruating fertile women show a positive reaction at this phase of the menstrual cycle. The usefulness of organotherapy in these cases is limited because one of the two ovarian hormones, "progesterin," so essential in the preparation of the premenstrual endometrium, is not obtainable for therapeutic use. The luteinization hormone from the anterior pituitary lobe, now available for therapeutic use, gives promise of therapeutic results.

Tuberculosis in American Negro—Pinner and Kasper compared the postmortem observations in 303 Negroes and 219 white patients who died of tuberculosis. They found a greater frequency of miliary tuberculosis in the Negro (37.3 per cent as against 15.5 per cent), a greater frequency of hematogenous metastases in the Negro (84.2 per cent as against 40 per cent), greater frequency of lymphatic metastases in the Negro (66.8 per cent as against 10.8 per cent), and various qualitative differences in the pattern of tuberculous lesions in the two races. The discrepancies that they observed led them to the conclusion that infection tends to produce a high state of allergy in the Negro but that he, unlike the white man, does not readily acquire a state of increased resistance coincidentally. Although the differences are not all mutually exclusive for the two races they are deemed to be of sufficient significance to warrant their serious consideration in explaining the well known discrepancies in the tuberculosis mortality rates and in the apparent individual resistance of Negroes and white persons.

The authors conclude that lack of childhood infection in the American Negro, often heralded as the cause of his inferior resistance, does not exist. They acknowledge the all important role of environmental conditions in the pathogenesis of the disease. But environmental factors are apparently not capable of explaining satisfactorily both the high mortality and the peculiarities of individual disease. They are impressed by the necessity of considering the likelihood of true genotypic differences between the two races in order to explain their different reactions to tuberculosis.

Tuberculosis in the Indian—From a survey of the mortality rate of tuberculosis among the Indians during the five years from 1927 to 1931, Burns observed that the Indian has a death rate from tuberculosis ten times greater than the white man. Racial mixing has not seemed to reduce the infection rate or the death rate from tuberculosis in the Indian population. The infection rate among the Indian school children is much higher than among the white school children living in the same county. There are no marked differences in the clinical types occurring among the various degrees of mixed bloods, full bloods and whites. The opportunity for contact over a long time seems to be the most important element explaining the prevalence of and the high death rate from tuberculosis. Tuberculosis in the Indian does not differ in any important essential from other communicable diseases. The Indian constitutes an important reservoir of infection which must be controlled to prevent the spread of the disease to the non-Indian population. It is quite apparent that the application of epidemiologic knowledge and public health practice can reduce the infection rates and death rates to their ultimate minimums among the Indian population.

Erythema Nodosum and Tuberculosis in Children—Dickey reviews the literature and states that in 100 per cent of sixteen patients under 15 years of age (observed at the Pediatric Service of Stanford University Medical School), suffering from erythema nodosum, a tuberculous infection has been proved, if one considers the intracutaneous tuberculin test as specific. A distinct majority of the patients were girls. All were hypersensitive to artificial tuberculin and most of them to minimal doses. Four of the rashes of erythema nodosum followed the inoculation of artificial tuberculin intracutaneously. In most of the patients a perifocal reaction was found in the chest by roentgenography. Six of the tuberculous infections were most probably initial. While it has been definitely proved that erythema nodosum may occur in children in the absence of allergy to tuberculin, and probably therefore in the absence of infection, one should consider this skin manifestation, when occurring in children, as evidence of an early infection or reinfection with the tubercle bacillus, unless there is definite proof to the contrary.

Peptic Ulcer—Martin gave intramuscular injections of milk protein to ninety-five patients suffering from peptic ulcer. Of these patients 78 per cent had been greatly improved or clinically cured at the end of treatment. At this time a greater percentage of those whose symptoms had existed for only a few months, 84.6 per cent, were clinically cured or improved. From one to four years after treatment, 60 per cent of the sixty patients who reported were clinically cured or improved. Of those whose symptoms had existed less than one year prior

to treatment, 77.9 per cent were improved or clinically cured. The majority of the author's patients had been on a general diet. The author believes that duodenal ulcer in man may be the result of a reaction of sensitized cells to a specific antigen and that the therapeutic aid brought about by the parenteral injection of milk protein may be due to a nonspecific desensitization of the sensitized cells.

Pulmonary Arteriosclerosis—Ulrich points out that the clinical bases for the diagnosis of pulmonary arteriosclerosis have been a delimitation of the heart which resembles a mitral or congenital type, the symptoms of an undue cyanosis and dyspnea not commensurate with the clinical observations, repeated hemoptyses with little evidence of infarct, radiologically a silhouette of the heart of a mitral or congenital type with increased hilus shadows, increased vascularity, and visible pulsation of the larger and sometimes pulsation of the smaller vessels in the lung field. To these he adds a new triad found in cases which clinically fit into the category of pulmonary arteriosclerosis, palpable pulsation in the intercostal spaces, a pulmonary souffle heard all over the chest, and the dance of the diaphragm (a fluoroscopic observation which consists in a down and up movement of the diaphragm synchronously with systole and superimposed on its respiratory movements). The author bases this triad on the assumption that, with increased arterial pressure and with the usual accompanying dilatation in the larger and medium sized vessels, the increased volume of blood, with increased force, entering the lung would make the lung pulsate much like the expansile pulsation of a congested liver in tricuspid insufficiency, or like the pulsation of a liver in aortic insufficiency when there is a marked water-hammer effect in the hepatic arteries. In a case of mitral disease which under the fluoroscope had exquisite pulsation of the pulmonary arteries well out in the lung areas, palpation of the interspaces gave a distinct impulse. This impulse is best felt in the second interspace to the left and right of the sternum, laterally in the interspaces in the midaxillary lines, posteriorly in the lower interspaces, and sometimes in the interscapular areas. It occurred to the author that there might be a vascular bruit due to the deformity of the pulmonary vessels. He found it so in his test case. The bruit is vascular, it must be differentiated and disassociated from cardiac noises transmitted by the chest wall. This bruit is heard all over the chest but can be most clearly heard in the left second interspace, in the right second interspace, and over the whole right side, particularly since the cardiac noises are heard less on that side. Again, he argued that if a lung pulsated as a whole to the extent that it was palpable through the chest wall it might be possible to see this effect on the diaphragm. Under the fluoroscope, particularly on the right side, following a deep breath, the down-and-up movement of the dome could be seen during expiration, synchronous with the heart beat. The author concludes that with this new triad an earlier diagnosis of pulmonary arteriosclerosis is possible.

Tuberculous Children—A ten year observation at Lymanhurst leads Myers to conclude that in the diagnosis of the childhood type of tuberculosis the tuberculin test and roentgen examination are superior to all other aids. The best type of tuberculin test is the intracutaneous method of Mantoux. The intracutaneous test is so specific that it constitutes a fine tuberculosis screen. The roentgenogram is a coarse screen when compared with tuberculin, as one is rarely able to detect lesions by its use in more than from 20 to 25 per cent of the children who give a positive reaction. Among 4,031 children reacting negatively to the tuberculin test there was evidence of questionable to definite childhood type of tuberculosis in 2.79 per cent, while among 4,737 children reacting positively to the tuberculin test such evidence of the childhood type of tuberculosis was found in 22.91 per cent. Among the 4,031 negative reactions the adult type of tuberculosis was found in 0.05 per cent, while among the 4,737 positive reactions the adult type of disease was found in 1.26 per cent. Among the negative tuberculin reactors no case of tuberculosis of the bones and joints was found, while among the positive reactors 0.52 per cent was found. The infant has an excellent tolerance for tubercle bacilli. The factors that seem to determine whether he survives or succumbs are dosage and continued exposure. The author's observations have convinced him that only those children with the first infection type of tuberculosis develop the

adult and destructive type. Therefore he does not see his way clear to consider the first infection type of tuberculosis as a protection to the child. He believes that the longer the first infection type of tuberculosis can be prevented in the human body, the better. The ultimate goal should be to reduce the possibilities of exposure so that one may live without the first infection type of tuberculosis appearing in the bodies of most people. The childhood type of tuberculosis usually comes under control without treatment. He believes that it rarely, if ever, kills as it occurs in nature, and he is of the opinion that the vast majority of such cases do not require hospitalization. Protection from further exposure to tubercle bacilli, and the use of energy producing foods, conservation of energy, and medical and nursing supervision, such as may be provided by special schools for tuberculous children, are all that is required. When the adult type of tuberculosis appears, if the home conditions are not good, sanatorium or hospital care is indicated, and such special treatment as collapse therapy is none too drastic.

Hypervitaminosis D—According to the experiments of Ham, enormous single doses of viosterol will produce massive calcifications in the aorta, coronary vessels and cardiac musculature of the rat as soon as forty-eight hours after administration. Sections from the tissues twenty-four hours after administration showed nothing that would presage such an imminent catastrophe, so that the calcification did not appear to depend on degenerative changes in the recipient tissues. The rapidity of formation, together with the massiveness of the calcifications, suggested that the prime factor in their causation was the inability of the serum to retain all its calcium in solution. The author suggests that precipitation depends on saturation of the serum with diffusible calcium and other factors. It seems probable that conditions suitable for precipitation could be more easily obtained as the serum calcium level is falling after the attainment of hypercalcemia. An inflammatory cell infiltration developed about the affected coronary vessels and about the calcified areas of cardiac muscle. His observations indicate that the toxic action of vitamin D does not depend on a quality separate from that on which its therapeutic action depends. The vitamin does not necessarily possess a specific toxic effect on tissues, but the calcifications of hypervitaminosis D can be explained by its action on the calcium metabolism. He also suggests that the calcifications of the variety that depends on the inability of the serum to retain all its calcium in solution depend for their causation to a greater extent on the level of the diffusible calcium than on the level of the serum calcium. He concludes that the so-called toxic effect of vitamin D demonstrated in his experiments was obtained only with enormous amounts of the vitamin, and that the doses used were infinitely beyond those utilized therapeutically in the administration of cod liver oil or viosterol.

Congenital Cyst of Lung—Stewart and his associates review the literature and report a case of congenital cyst of the lung, in a woman, aged 54, in whom the majority of the distended bronchi communicated with the main bronchial tree. A few had no such connection, and they were therefore true cysts. These may have enlarged during postnatal life. The majority of the distended bronchi ended blindly. A few terminated in functioning alveoli which accounted for the variation in their presentation. As associated factors hypertrophy of the right side of the heart and sclerotic changes of the pulmonary artery

and polycythemia were found. The physical sign observed, indistinguishable from a pleural friction rub over the entire chest, is of diagnostic import. The authors state that until more information is available such malformations should be classified under the general term of "congenital cyst of the lung."

Parathyroid Hormone—On the basis of experiments on rats, McJunkin and his associates state that the parathyroid hormone inhibits mitotic proliferation of the parathyroid in amounts insufficient to produce hypercalcemia and destructive lesions of parenchymatous organs. The lesions produced by excessive doses of the hormone are toxic and primary. The circulatory failure that characterizes the fatal cases is secondary to the destructive lesions in the myocardium. The hormone when brought into direct contact with parenchymatous cells produces lesions analogous to those produced after its absorption into the blood stream. Necroses are produced in the kidney and heart by intraperitoneal injection of calcium gluconate alone. It is probable that the hormone and calcium gluconate as well as viosterol injure parenchymal cells by disturbing the calcium components of the tissue fluids of the cells themselves. There is no evidence of metastatic calcification in the rat in the sense that the calcium is deposited in tissue otherwise normal. In the rat, local degenerations of the tissues are primary and precede calcification. Amounts of hormone insufficient to produce effects demonstrable by the methods previously used successfully arrest mitotic proliferation of the parathyroid. Amounts not large enough to elevate the serum calcium may cause myocardial lesions. Inactivated hormone, completely inert as determined by the usual method employed for testing activity, arrests parathyroid proliferation but produces neither hypercalcemia nor destructive lesions.

Arch. of Physical Therapy, X-Ray, Radium, Chicago

Radium Treatment of Toxic Goiter—According to Ginsburg, under the term toxic goiter are included all types of nonmalignant goiter associated with tachycardia, tremor, wasting, increased basal metabolic rate, and nervous and mental manifestations, with or without exophthalmos. Clinically, the three main groups are diffuse toxic, nodular or adenomatous toxic, and nodular and diffuse toxic goiter. Pathologically, no fundamental distinction is recognized among the various types of toxic goiter. They are looked on as mere variations of a single disease. The entire gland is usually involved in the pathologic process in primary diffuse toxic goiter, while discrete areas are involved in nodular goiter, with intervening healthy tissue between the affected areas. In the pathogenesis of primary as well as secondary exophthalmic goiter, a definitely diseased thyroid assumes a predominant and central role. In addition to general supportive and symptomatic measures and removal of foci of infection, local treatment directed toward the thyroid is of paramount importance. The etiology of exophthalmic goiter still remains unknown. Medical treatment of the disease, although merely symptomatic and supportive, has yielded good results in many mild and some moderately severe cases. The mortality of mere medical treatment of severe cases of thyrotoxicosis has been recorded as high as 11, 17 and 38 per cent, in the experience of different observers. Surgical treatment, in spite of improvement in technique and preoperative use of iodine, still carries a mortality of between 0 and 27 per cent. Nor does recovery from the operation always mean complete clinical cure of the disease. Radium therapy efficiently applied yields as brilliant results as surgery or even more brilliant results, without the attendant mortality and postoperative complications of surgical procedures. To obtain such results, proper selection of cases must be made. The types of cases in which radium therapy is indicated are (1) borderline, mild or larval cases, (2) early cases, (3) cases presenting slight thyroid enlargement, (4) the aver-

age case without compression, (5) postoperative persistent or recurrent cases, (6) severe cases, without compression, in which operation is refused, and (7) poor operative risks. Radium therapy should always be combined with judicious medical management. Surgical therapy is indicated in (1) cases refractory to radium therapy, (2) cases presenting compression phenomena, (3) severe cases in which quick economic restoration is required, and (4) cases presenting large, long standing, adenomatous goiters, in which perfect cosmetic results are demanded.

Diathermic Treatment of Pneumonia—Stewart states that the treatment of pneumonia by diathermy is steadily gaining favor whenever it has been given an adequate clinical trial. Clinical improvement sufficient to justify the employment of diathermy is attested by every writer on the subject. A more general knowledge of the efficiency of early treatment on the part of the profession at large will lower the mortality figures. The use of diathermy in pneumonia affords a measure of the greatest value in the treatment of each case.

Bronchoclysis—Mandelbaum believes that bronchoclysis permits prolonged local application of remedial agents in isotonic aqueous solution to lesions of the bronchopulmonary organs and a flushing of the rich bronchopulmonary lymphatic system as a result of the ability of the lower respiratory canal, after preliminary local anesthesia, to retain catheter-like instruments of fine caliber for longer periods than heretofore found possible. The procedure is initiated by the insertion of a specially curved, cotton-tipped pyriform-sinus applicator, moistened with a freshly made 10 per cent solution of cocaine, in each pyriform sinus, first on one side and then on the other. It should be held in position from one to two minutes and after an interval of ten minutes should be inserted again. As bronchoclysis requires the prolonged retention of the catheter in the tracheobronchial canal, it is best to instill a few drops of a warm 2 per cent solution of cocaine on the vocal cords as well as between them into the trachea by means of a specially made syringe with a tracheal curve. After the anesthetic has taken effect, the wire stylet should be anointed with sterile olive oil, liquid petrolatum or iodized poppy-seed oil, before slipping it into the catheter, to permit its easy withdrawal when the catheter is in situ. With the patient sitting in the usual position for laryngologic examination and the laryngoscopic mirror in place, either the patient himself or an assistant holds the extended tongue. The tip of the styleted catheter is inserted between the vocal cords while the patient is asked to take a deep inspiration. When the instrument has passed several inches below the cords, the tongue is released and the stylet withdrawn, while one hand fixes the position of the catheter at the upper teeth and the other grasps the proximal end. When the catheter is quickly and most gently slipped farther down toward the carina of the trachea and the wire stylet withdrawn, the patient is told to close his lips firmly on the catheter and to breathe slowly and regularly through his nose. Then the rubber tubing is connected by means of the free end of the double glass connecting tube by inserting it into the proximal end of the catheter held between the patient's teeth or by the operator's fingers. The fluid is allowed to flow into the desired region and the rapidity of the flow slowly increased up to from 40 to 50 drops a minute until from 15 to 25 cc. has been injected, which is sufficient for the first treatment. It is better to give small amounts frequently at first, in some cases from 15 to 25 cc. as often as every other day, and, as a tolerance is established, gradually to prolong the intervals with the increased amounts instilled until a drip rate up to 60 drops a minute and a quantity of from 500 to 600 cc. may be tolerated. Isotonic, isothermic solutions, either plain Ringer's solution or similar aqueous mediums, with the addition of antiseptic agents of bacteriostatic potency such as acriflavine, acriflavin, acriflavine and metaphen, have been used with excellent effect in all forms of purulent bronchopulmonary lesions and in cavitations, both tuberculous and nontuberculous, without untoward results. Their particular value in tuberculous cases is a symptomatic relief, apparently due to the effect on the secondary infecting organisms. They have also exerted a favorable influence in cases of bronchial distress following military gassing. Bronchoclysis should not be used during the early or acute febrile stage of bronchopulmonary disease.

Toxemias of Pregnancy—Hurwitz and Ohler observed that blood chemistry tests, phenolsulphonphthalein and one hour tests did not help in the differentiation between chronic nephritis and acute toxemias. In the 103 urea clearance tests done on sixty-four patients falling in groups of normal pregnancy toxemias, eclampsia, patients who had toxemia in a previous pregnancy and chronic nephritis patients, the urea clearance checked up well with the clinical diagnoses with only a few exceptions. It was found to be higher than the usual normal limits in normal pregnancy, normal in toxemias, decreased in the acute stage of eclampsia (with a tendency to a rapid return to normal in one case), and low with a high degree of consistency in chronic nephritis. The data suggest a correlation between the high urea clearance and the low blood urea nitrogen in normal pregnancy.

Gastric Juice in Pernicious Anemia—Helmer and his associates studied the gastric juice of forty-seven patients with pernicious anemia and of ten normal persons, after histamine stimulation. The complete dysfunction of the gastric glands in patients with pernicious anemia was demonstrated by the following facts: (1) small volumes of juice containing large amounts of mucus, (2) absence of free hydrochloric acid, with an actual alkaline reaction, (3) practical absence of the gastric enzymes pepsin and rennin, (4) low chloride concentration, (5) high nitrogen and phosphorus values, and (5) no relation between total acid, pH , chlorides, nitrogen and phosphorus as found in normal controls. The quality and quantity of the gastric juice of patients with pernicious anemia has little or no relationship to the maintenance dosage of liver extract.

Exophthalmic Goiter—Hertz and Lerman believe that the discrepancies in the literature as to the blood picture in exophthalmic goiter are probably due to misclassification of the monocytes, a source of error which is reduced to a minimum by the use of the supravital technic. The most marked and characteristic observation in the blood of patients with exophthalmic goiter is a relative and absolute monocytosis. Leukopenia and hypopolynucleosis are the rule. The percentage of lymphocytes is increased above normal in most cases. The basal metabolic rate shows a direct correlation of probable significance with the percentage of monocytes and of polymorphonuclears, respectively, and an inverse correlation of the same order with the percentage of lymphocytes. There is no relationship between the level of metabolism and the total leukocyte count. The most characteristic effect on the blood picture of exophthalmic goiter from the administration of iodine is a reduction both in percentage and in absolute number of monocytes. In addition, there is a moderate decrease in percentage and absolute number of lymphocytes, and a significant increase in the percentage but not in the absolute number of neutrophils. The total number of leukocytes decreases in most cases. The reduction in the number and percentage of monocytes tends to be proportional to the reduction in the basal metabolic rate. The changes in the other cell elements and in the total leukocyte count do not show any such relationship to the basal metabolic rate. The immediate effect of operation is to increase the total number of leukocytes, owing chiefly to the increase in the number of polymorphonuclear cells and monocytes. Only the percentage of monocytes is significantly changed. The final changes in the blood picture following operation are qualitatively the same as those produced by iodine. The total white blood cell count is reduced slightly. The reduction in metabolism is proportionately greater than the change in the blood picture.

Sexual Development of Boys—Kubitschek presents a study which represents the results of an examination of 730 boys, aged from 9 to 18 years, concerning their sexual development. Structural type and personality makeup. From this study he concludes that sexual development in boys is slow between the ages of 9 and 12 and rapid between the ages of 13 and 15, again slowing up after the fifteenth year. The development of the primary sex characters usually precedes that of the secondary sexual characters and is most marked during the thirteenth and fourteenth years. The secondary sexual characters develop at a more uniform rate over a longer period. He found a marked variation in both the time of onset and the rate of development of both primary and secondary sexual characters. This was particularly true in the 13, 14 and 15 year group. Variation in age and rate of sexual development in Negro boys corresponded closely to that of

the white boys. Striking variations between the degree of development of the primary and secondary sexual characters were frequently encountered. An interesting relationship was found between structural type and development of secondary sex characters, retarded development predominated in those of asthenic habitus, advanced development predominated in those of athletic and pyknic habitus. No definite relationship was established between structural and personality types.

Bismuth Subnitrate in Arterial Disease—Stieglitz believes that successful curative therapy in hypertensive arterial disease involves the eradication of active etiologic sources of arteriolar irritation and arteriolar relaxation with mild vasodilatation sufficiently prolonged to permit of rest of the fatigued and hyperirritable neuromuscular apparatus. Bismuth subnitrate, through the gradual prolonged liberation of nitrite ions in the intestinal tract, is a mild but persistent arterial dilator, or arterial sedative. Bismuth subnitrate not only reduces the arterial tension in spastic hypertonia during the period over which it is administered but, if the administration is prolonged sufficiently to permit of arteriolar rest, the arteriolar hypertonia frequently does not recur. It assists in reduction of the physiologic burden of the injured structures, namely, the medial musculature of the arterioles. The therapeutic results obtained in hypertensive arterial disease with bismuth subnitrate evaluated several years after the institution of therapy are most encouraging and gratifying. In the presence of extensive arteriolar sclerosis or active etiologic sources of arteriolar irritation, bismuth subnitrate is inadequate, as would be any other mild vasodilator. Bismuth subnitrate is nontoxic in the dosage employed, 30 grains (2 Gm.) a day or less. In angina pectoris associated with hypertensive disease, bismuth subnitrate appears to reduce the frequency and severity of anginal attacks.

 *Laryngeal Stenosis Growth of Larynx as Factor in Treatment. C Jackson and C L Jackson, Philadelphia—p 887

Laryngeal Stenosis—The Jacksons consider that the greatest factor in the successful treatment of stenosis of the larynx in children is the increase in size of the larynx during the period of general growth of the child. To obtain the utmost advantage of growth, however, it is necessary to maintain a lumen and to force the child to breathe through it, by partial corking of the cannula. The larynx will not grow properly or adequately if the child is allowed to breathe freely through the neck. In most cases the lumen can be maintained by direct laryngoscopic dilation, combined with graduated continuous corking, over a long period of time. In a few cases other methods by rubber tube or otherwise are necessary, but, whatever the method, the most important thing is to force the growth of the larynx. The utmost conservatism as to surgical procedure is fundamental in dealing with the larynx of a child. Radical measures, especially when accompanied by the removal of tissue or destruction of cartilage by secondary suppuration, may ruin the larynx beyond hope of cure.

Postoperative Exophthalmic Goiter—Bram found that, out of a total series of nearly 4,300 cases of exophthalmic goiter, 562, or approximately 13 per cent, occurred in patients

who had undergone one or more thyroidectomies. Postoperative exophthalmic goiter may occur in the following forms: persistence in varying degree of the original syndrome without an intervening period of apparent normality, recurrence of symptoms after weeks, months or years of apparent normality, the existence in combination of so-called hypothyroidism and hyperthyroidism with or without a brief period of apparent well being immediately following thyroidectomy, persistence or recurrence of the symptoms with a complicating acromegaly, and persistence of the syndrome with the superimposition of a major psychosis, usually in the form of manic-depressive insanity. The author concludes from his observations that exophthalmic goiter is not synonymous with hyperthyroidism nor is it primarily a disease of the thyroid. In the treatment of a syndrome the etiology of which is still unknown, it would also appear that the clinical habit of taking thyroidectomy for granted as the logical therapeutic measure calls for reconsideration. The author reports six cases that are illustrative of this condition.

Treatment of Traumatic Strictures—Muellerschoen points out that from 85 to 90 per cent of strictures may be cured by gradual dilation when the patient will cooperate. Internal urethrotomy may be indicated in permeable strictures of gonorrheal origin. Strictures complicated by sinus, gross infection, fibrosis, resilience, false passage or multiple narrowings demand at least an internal and external urethrotomy combined. This procedure may not suffice. Urethrectomy is practiced when possible in instances of extreme resilient fibrosis, in angulation and marked sinus and in angulation or vicious anastomosis of the channel. Urethrostomy is the choice if the other methods have failed. Suprapubic drainage is the last recourse. It is often an emergency operation. Some cases after a drainage period may warrant more refined surgical attempts such as urethrectomy or urethrostomy. One should impress on the patient the importance of continued dilation after the stricture has been dilated to its normal caliber at regular intervals.

The Neurotic Patient.—Menninger classifies the neuroses into what are called actual neuroses and the psychoneuroses. The actual neuroses exhibit themselves primarily as physical disorders and the causative factors are predominantly physical in character. The psychoneuroses, on the other hand, do not present any physical basis but exhibit themselves primarily as strictly mental disturbances. They are psychogenic in origin, with responses conditioned entirely by the individual's development. The primary cause for the neurosis is a persistence of infantile trends or infantile behavior patterns or groups of cases centering around an abnormal psychosexual development, either by arrest or by distortion of the normal development of the individual, or by the process of regression. To understand the nature of the neuroses, one must understand not only the etiology factors but also the psychologic steps that take place in the individual to make him develop the symptoms of physical complaints, hysterical paralyses, fears, compulsions and the like. If one fully understands the psychologic nature of the neuroses, one should be able more adequately to fit the treatment to the illness. It is essential to recognize that one cannot treat a psychologic illness simply with physical measures, with any more success than one can treat physical illness with merely psychologic measures. The author concludes that the treatment must depend on the type and the stage of development of the neurosis and should be physical, environmental or psychologic.

Chronic Suppurative Otitis Media—Maness presents the results in a series of sixty-eight patients with chronic suppurative otitis media treated with iodine powder. His method of treatment was as follows. Polypi or granulations were removed from the middle ear as thoroughly as possible. Contributory causes, such as the adenoids or tonsils, were removed, or paranasal sinusitis was treated. Some patients refused to have their tonsils and adenoids removed. All irrigations and medications in the ears were prohibited. Careful attention against getting water in the ears was advised. All secretions were removed as thoroughly as possible from the external auditory canal and middle ear by means of cotton applicators. Gentle suction is advised as an aid to freeing the middle ear of secretions. The careful removal of all secretions possible is of vast importance, if success with the treatment is to be expected. In the insufflation of a 2 per cent iodine powder, it is important that as much of the powder as possible reaches the middle ear through the perforation. Treatments were given two or three times a week depending on the quantity of secretion. The more abundant the secretion, the more rapidly is the powder dissolved. The author concludes that a small number of chronic otorrheas develop fatal complications. The radical mastoid operation is associated with considerable mortality risk and should be resorted to only when conservative treatment has failed or when definite indications other than a chronic draining ear are present. The dry treatment of chronic suppurative ears is the best nonoperative measure. Chronic suppurative ears should not be treated by repeated irrigations. Iodine dusting powder is a valuable adjunct in the treatment of chronic suppurative otitis media. Obtaining a dry ear is no guaranty that recurrence of drainage will not occur. All contributory causes of chronic middle ear suppuration should be removed if possible.

Displacement of Upper Femoral Epiphysis—Taylor reports the results of a study of twenty-three cases of displacement of the upper femoral epiphysis. Of these, thirteen were under observation long enough to make it possible to consider the results obtained by treatment, while ten were recent. No cases were recorded in which the history and roentgenograms did not definitely establish the diagnosis. In persons over the age of 25 it is often impossible to distinguish roentgenographically between old cases of "slipped epiphysis" and old cases of Perthes disease. Such cases were excluded. Both from the history and from the roentgenographic appearances it was possible to differentiate two types of displacement. First, the type due to a single gross trauma, in which the condition is probably one of fracture through the juxta-epiphyseal line, though it is held by some that the separation takes place through the actual epiphyseal cartilage. In this type there is definite, complete loss of continuity between diaphysis and epiphysis. The second type is that in which the deformity develops gradually and there appears to be a bending of the neck of the femur, somewhat similar to that seen in the softened long bones of the rachitic child. The pathologic anatomy of the condition preceding the actual slip is obscure. Gentleness of manipulation and prolonged protection from weight bearing are essential features in the treatment. Prolonged extension on a frame appears to be the most suitable form of "manipulation" in the gradual slip type.

Varicella in Old Age—Rolleston gives the case history of a woman, aged 76, whom he had been asked to see in his capacity as one of the smallpox consultants to the London County Council. The patient's age and the severity of her illness suggested the possibility of smallpox. The distribution of the lesions, however, and their size, shape and multiformity, as well as the history of their appearance on the first day of disease, indicated chickenpox. The diagnosis, moreover, was subsequently confirmed by a history of exposure to the disease within the previous fortnight at a hospital where she had been under treatment by high voltage roentgen therapy for lymphosarcoma. On admission to the hospital there was considerable constitutional disturbance and the temperature was 102 F. The presence of lymphosarcoma was indicated by enlarged lymph nodes in the neck, axillae and groins. In addition to its typical appearance and distribution elsewhere, the eruption of chickenpox was confluent over the parts of the left side of front and back of the chest and left arm, where she had undergone roentgen therapy. The temperature finally became settled on the third day after admission, and there was a rapid improvement in the general condition. The lesions in the area in which the eruption was confluent showed some tendency to ulcerate, but ultimately complete healing took place and the patient was discharged without any complications having occurred. There also appeared to be some diminution in the size of the enlarged lymph nodes in the axillae at the time of her discharge.

Note on Pathologic Museum (Otolaryngologic Section) of British Medical Association Centenary Meeting, July, 1932 E D D Davis and T Cawthorne—p 756

Malignant Disease of the Larynx and Pharynx—Stewart-Harrison discusses the principles that are involved in the protracted-fractional method of applying high voltage roentgen treatment, describes the details of the method in its application to tumors of the larynx and pharynx, and presents a series of illustrative examples showing variation from case to case. The technic may be summarized as follows: A stabilivolt transformer, Müller tubes, a tube tension of at least 170 kilovolts and tube current of 3 milliamperes are employed. The radiation is filtered through 1 mm of aluminum and 13 mm of copper and the resultant half-value layer is equivalent to 135 mm of copper. The focus-skin distance varies between 65 and 75 cm; it is adjusted to a radiation intensity of 25 roentgens a minute measured in air (r/l a minute), a delivery of 36 r/l a minute at a focus-skin distance of 50 cm. The chosen fields include the primary tumor and the area of regional metastases. For all tumors two lateral fields are employed and in the case of tumors of the hypopharynx and larynx often three. The size of the fields is measured and from the curves of Jacoby and Liechti the intensity of the radiation on the surface (r/o) can be estimated. For example, for a field size of 200 sq cm 500 r/l will be necessary to produce a skin erythema. For a standard field (48 sq cm.), according to the author's measurements, 600 r/l is necessary for a skin erythema. The surface dose is therefore $6/5$ the dose measured in air. It is the therapeutically important dose and is referred to as r/o . When no contraindications are present, the patient is irradiated daily on the side of the lesion. On five days in the week, one of the other fields is treated in addition. With infrequent exceptions, 180 r/l is applied at a single sitting. He reviews 144 cases of malignant disease of the larynx and pharynx and summarizes the results of the treatment since its introduction to Zurich by Schinz in 1929. The local success figure is defined as the number of patients who have become free from signs and symptoms as a result of the treatment and up to the present time have not developed a local or regional recurrence. The optimal percentage local success is the ratio of this figure to the number of cases in which the treatment has been completed. Since results over a period of five years are not available, the figures for the optimal local success have been evaluated and its advantages and disadvantages discussed. The proportion of local success in this series is 55 per cent. The results are analyzed on a basis of the situation, nature and extent of the various growths. The results obtained in Zurich, 1919-1928, together with the results of some other authors, are similarly analyzed for the purpose of comparison. No attempt has been made to be all inclusive. The author concludes that the protracted fractional method of roentgen treatment is the treatment of choice in tumors of the epipharynx, mesopharynx and hypopharynx. In the case of the larynx it should always be taken into consideration.

Malarial Therapy in Dementia Paralytica—Since the introduction of malaria therapy for the treatment of dementia paralytica, the percentage of good remissions in Nicol's female cases at Horton is low compared with the results of other observers. There is little to be found in the literature concerning the disease as seen in the female. Leroy and Medakovich, in a communication on paralysis in the female, write that the disease is less severe and tends to follow a more insidious course. They also report that the disease in women is more advanced before they become certified. This may explain the high percentage of dementing forms in his series. The predominance of the dementing form in women is probably responsible for the lower rate of remissions following treatment. The material the author has to work on is mixed, the age incidence and duration of disease vary within wide limits, the proportion of the different clinical types is unequal. From the point of view of prognosis he lays most stress on the clinical type assumed and on the duration of the disease before treatment. His experience is that remissions are obtained by the first course of fever and that subsequent courses of malaria exert no influence on the mental or physical progress. Benign tertian malaria is the most convenient species, but access should be available to quartan malaria for those patients who are immune to benign tertian malaria or who are in a poor state of health, which might be endangered by the more severe type of fever. Whether second and further courses of malaria are necessary to maintain the latency or suppression of the syphilitic process cannot yet be decided. When desirable, the author has an ample source of treatment methods in the different species of malaria, including malignant tertian malaria, provided the patient can be assured of skilled and trained supervision. He concludes that the application of malaria to medicine has opened a new field of research, not only in malaria itself but in the disease to which it is applied.

Dementia Paralytica—Reid presents the after-history of patients treated by malarial inoculation for dementia paralytica since the introduction of this method of treatment at the Whittingham County Mental Hospital in July 1922. He states that, of all the patients suffering from dementia paralytica treated with malaria, 31 per cent are sent home improved each year. From six to nine years after treatment with malaria, 12 per cent of the patients have recovered from their illness and are living at home. From one to five years after treatment, 24 per cent of the patients have recovered and are living at home. Malarial treatment improves the physical condition of the patients suffering from dementia paralytica even when mental improvement does not result. Seventy-six per cent of the patients are living one year after treatment, 50 per cent four years after treatment and 22 per cent nine years after treatment. Malarial treatment of these cases admitted to the hospital is not without danger, and 13 per cent of the patients die within one month of inoculation. The prognosis is best in those patients who have had symptoms of the disease present for seven months or less prior to treatment. Reinoculation with malaria is of no special benefit in the treatment. Malarial treatment has little or no effect on the physical signs present in the nervous system.

Blood Cholesterol and Hyperglycemic Index in Manic Depressive Psychosis—A sustained hyperglycemia and quantitative changes in the blood cholesterol are common observa-

tions in the manic depressive psychoses, and, since both may be dependent on a faulty endocrine balance, parallel observations of the hyperglycemic index and blood cholesterol have been made by Lockwood in twenty-four cases in order to determine whether any relationship exists between the two values. She found that a relationship does exist between the values. The blood cholesterol content showed a delay in the return to normal as compared with the dextrose tolerance curve. When the hyperglycemic index falls to zero, the cholesterol level lies at the upper limit of normal. A rise in the hyperglycemic index was associated with quantitative changes in the blood cholesterol of such a nature that the two values bore an inverse ratio to each other. In three cases in which the test was repeated at different phases of the illness, variations in the hyperglycemic index were accompanied by variations in the cholesterol level.

Brain Tumors—Merritt and Moore report two cases of glioma of the anterior portion of the corpus callosum and frontal lobes which showed a turbid cerebrospinal fluid. They discuss the literature on this subject and explain the presence of the polymorphonuclear cells in the cerebrospinal fluid of cases of brain tumor as being due to drainage of cells from the area of symptomatic inflammation occurring around foci of necrosis close to the ventricles.

Mental Changes in Pernicious Anemia—According to Piney, it might be profitable to examine the blood in all cases of mental disorder in which there is even the slightest clinical evidence of anemia. In a case observed by him, complete restoration occurred. It is particularly interesting to observe that the disappearance of the mental symptoms preceded the cure of the anemia. The very fact that suitable treatment of the blood may be followed by cure of the mental condition suggests that such patients should be kept in their own homes or in the wards of a general hospital for a month or two instead of being certified immediately. If this were done, much distress might be avoided, as presumably a considerable percentage of cases would be saved from the stigma of insanity. It seems almost certain that, if the pernicious anemia and the mental symptoms have persisted for a long time, the latter will not respond to treatment even if the former is adequately dealt with. In the last stages of a case in which treatment has been long delayed, complete dementia will inevitably develop.

2: 1145 1198 (Nov. 26) 1932

- Liberal Education of the Body. L. P. Jack.—p. 1145
 Hematuria. A. Fullerton.—p. 1149
 Hypertensive Retinitis. D. McAlpine.—p. 1152
 Cases Tensions in Lateral Ventricle of Brain. J. A. Campbell.—p. 1156

Hematuria—Fullerton gives the present status of the treatment of hematuria. In severe cases the patient should be kept at rest in bed and morphine if not contraindicated should be administered. Calcium chloride or lactate should be given for a few days. Preparations of ergot may be tried and sterilized horse serum or inhalation of carbon dioxide as recommended by Wright may be of use. Above all the underlying cause must be sought and treated. Tumors, calculi and tuberculosis demand surgical treatment if suitable for operation. Renal hematuria of the type known as essential may tax the resources of the surgeon to the utmost. Decapsulation incisions into the pelvis to deal with the papilla is involved and incision into the parenchyma have all been tried without success in such treatment. If the surgeon is satisfied that no grave disease is present instillation into or irrigation of the pelvis or the kidney with solutions such as those of

silver nitrate may succeed in arresting the hemorrhage. Removal of the offending organ is a radical procedure justifiable only if all other methods fail and the patient's life is in danger. To control hemorrhage of bladder origin, pending more radical measures, epinephrine may be employed. A more lasting effect may be produced by irrigation with silver nitrate solution. If massive clotting has taken place, an evacuating catheter, similar to the catheters used for litholapaxy, may be used to remove the clots. It may even be necessary to perform cystotomy. Raising the foot of the bed by diminishing the blood supply may be of service in some cases. The author has never found it necessary to pack the bladder. Bleeding from the anterior urethra can be arrested by pressure. Bleeding from the bulbous or membranous urethra may be controlled by pressure applied to the perineum. Finally, no patient ought to be allowed to die of hemorrhage without an attempt being made to restore him by blood transfusion or intravenous injection of such preparations as gum saline solution.

Hypertensive Retinitis—McAlpine believes that the term "hypertensive" should replace that of "albuminuric" or "renal," as suggested by Fischberg and Oppenheimer, because the retinal changes, usually described under these names, may occur in the absence of any appreciable renal disease. Moreover, evidence is accumulating in favor of the effects of a widespread arteriolar constriction, the results of which may also be apparent in the fundus, brain, heart and extremities. It is true that the resulting changes in the kidney frequently lead to a fatal termination in uremia, but this fact does not warrant the use of the adjectives "albuminuric" or "renal." In other cases, a form of true nephritis has been the cause of the hypertension, the latter, however, is the agent responsible for the retinal changes. The adjective "hypertensive" expresses the essential factor—hypertension—whether this precedes or follows renal disease. This form of retinitis is commonly seen in persons under the age of 50. The hypertension, which is usually marked, may develop rapidly or, having been present for some years, may show a sudden accession. Constriction of the retinal arterioles is the earliest change, and this is followed by retinal edema, hemorrhages and exudates, which initially may take the form of cotton-wool patches. The balance of evidence seems to favor the view that such changes are due to ischemia. In young persons there may be no signs of retinal arteriosclerosis at the commencement, and therefore the retinal changes may occur independently of degenerative changes in the walls of the vessels, although, if the hypertension persists, these will share the fate of the arterioles in other parts of the body. Papilledema, though frequently present, is not a necessary accompaniment of the retinal changes, if mild in degree and accompanied by peripapillary edema it may be caused solely by local circulatory disturbances. When marked, the principal factor in its production is cerebral edema. Its presence adds to the gravity of the case.

*Arsphenamine Erythrodermia. G Garnier—p 557

Arsphenamine Erythrodermia—Garnier reviews the symptomatology, diagnosis and treatment of vesiculo-edematous erythrodermia due to arsphenamine therapy. It occurs after the fifth or sixth treatment (or later) and is not to be confused with the erythema of the ninth day. The prodromal symptoms are pruritus, edema and localized erythema. The localized erythema rapidly develops into a generalized erythema characterized by vesiculation, edema and desquamation. The edema is generalized and severe, it is chiefly dermic, hard and elastic. The vesiculation predominates on the extremities and gives rise to profuse oozing resulting in yellow crusts, when the vesicles rupture. Desquamation starts about the tenth day and is abundant. The general symptoms in addition to fever are oliguria, edema and increase in weight. The erythrodermia lasts from six to eight weeks and usually ends in recovery but may terminate fatally through supervening infection or purpura or, occasionally, marasmus. Prognosis is good if the weight decreases, the urines increase and the temperature drops, if the weight decreases rapidly while the oliguria and the elevation of temperature persist, infectious complication is probable. In rare cases the erythrodermia may be segmentary. Sometimes the beginning of the erythrodermia is masked by an eruption of lichen planus which is suddenly transformed into erythrodermia. Spontaneous recurrences of light form and short duration may occur. Renewal of arsphenamine treatment produces an immediate recurrence, even after several years. Keratoderma and melanoderma are frequent sequels. The vivid redness of the beginning local erythema distinguishes it from a vesicular eczema. After the erythema is generalized, it is distinguished from the erythema of the ninth day chiefly by its late appearance and the absence of an infectious syndrome. Once established, it can be differentiated from other erythrodermias only by knowledge of the arsphenamine treatment. Preventive treatment consists in keeping the arsphenamine dosage within the maximum of 0.015 Gm per kilogram of weight and interrupting treatment immediately on the appearance of prodromal symptoms. The treatment of confirmed erythrodermia consists in the daily administration of about 90 drops of a 1:1,000 solution of epinephrine combined with diuretic treatment. Early treatment is important and may sometimes prevent vesiculation and oozing. The appearance of erythrodermia is an absolute contraindication for the future use of arsphenamine. In persons who have had an arsphenamine erythrodermia, the intradermal injection of 0.1 cc of a 1:100 solution of arsphenamine produces a cutaneous reaction years after the attack. The author considers arsphenamine erythrodermia a toxic phenomenon depending on alterations of the sympathetic system.

*Medullary Complications of Leukemias. J. Olmer and J. Alliez—p 1986

Medullary Complications of Leukemias—Olmer and Alliez report the case of a man aged 49, with myeloid leukemia who, after two months of intense dorsal pain, developed progressive flaccid paraplegia, becoming rapidly total, and syringomyelic dissociation of sensibilities. The spinal fluid was xanthochromic, was spontaneously coagulable, and exhibited albuminocytologic dissociation. The disease exhibited an ascending progression of the Landry type and the patient succumbed in several days under bulbar symptoms. At necropsy a small tumor of myeloid leukemic type, a veritable metastatic myeloblastoma, was found on the level of the second and third dorsal vertebrae with a meningeal and vascular infiltration, which had caused myelomalacic lesions owing to a necrotic process following vascular thrombosis. The author says that most of the medullary complications of leukemia that have been reported occurred in myeloid leukemia, usually in males. Clinically the two essential characteristics of medullary complications are the intensity of the pains that mark the beginning, and the rapidity of the onset and evolution of the paraplegia.

When this syndrome is seen, one should always think of leukemia, as the medullary complications may occur in a leukemia that has not been diagnosed. Anatomically, the medullary complications may be of three types: local or diffuse leukemic infiltration of the spinal cord, vascular lesions, chiefly necrotic softening of the spinal cord following thrombosis, and lesions secondary to compression of the spinal cord.

Hysterosalpingography—On the basis of their experience with 500 hysterosalpingographies, Francillon-Lobre and Dalsace discuss the indications, contraindications and technic of this method of examination, the interpretation of the roentgenograms, and their diagnostic value. In cases of sterility in which clinical examination of the woman and her husband has revealed no cause for the sterility, hysterosalpingography often permits diagnosis. However, it is not sufficient to inject the iodized poppy-seed oil into the uterus and take a few roentgenograms, it is necessary to study physiologically the filling, the contractions and the emptying of the uterus and the oviducts. Hysterosalpingography is also indicated in cases in which minute clinical examination fails to establish the cause of metrorrhagias, repeated abortions or various gynecologic disturbances, or in the presence of a pelvic tumor that cannot be exactly delimited. In these cases the roentgenogram is a valuable element of diagnosis, particularly if there is close collaboration between the roentgenologist and the gynecologist. In addition to pointing out the diagnostic value of hysterosalpingography in these various abnormal conditions, the authors recommend it as a therapeutic measure of the first rank in sterility. They found that a fairly high percentage of the young women on whom hysterosalpingography was performed for purely diagnostic purposes became pregnant in the months following the intervention.

*Erythema Nodosum and Tuberculosis. A. Laurinsich—p 1309

Congenital Malaria Case. A. Pinelli—p 1317

Erythema Nodosum and Tuberculosis—Laurinsich reviews the literature and states that 96 per cent of all patients with erythema nodosum show a positive reaction to tuberculin. The allergy in erythema nodosum does not follow eruption but is already present during the stage of prodromal fever, some authors maintain that it is most intense previous to eruption. The nodose eruption appears as soon as tuberculin allergy commences. This is substantiated by the fact that allergy is present before the eruptive fever, hyperallergy taking place afterward. Therefore, the beginning of erythema nodosum coincides with the end of the period of incubation of tuberculosis. Erythema nodosum, like tuberculosis, occurs mainly in the spring. The author experimented with forty-five patients and obtained positive skin reactions to tuberculin in all of them. He concludes that erythema nodosum is a cutaneous manifestation of a primary tuberculous infection or of the awakening of a latent infection and therefore he considers it an allergic phenomenon.

*Perforated Right Pyosalpinx Simulating Acute Appendicitis Case. G. Selvaggi—pp 775

Right Pyosalpinx Simulating Acute Appendicitis—Selvaggi reviews the literature and cites the case of a woman, aged 26, with a ruptured pus tube on the right side simulating acute appendicitis. The author states that the perforation is found most often in the ampullar portion, rarely at the uterine insertion. The perforation varies greatly in size. The margins are always well defined and surrounded by a necrotic portion. The symptomatology consists of intense pain, vomiting, shock, small frequent pulse (129-140), shallow respiration of costal

type, rise of temperature (38.5-39 C or 101.3-102.2 F), and rectal tenesmus with empty ampulla. The course of acute perforation of pyosalpinx consists of 1 The phase of shock corresponding to the perforation itself, characterized by sudden and violent pain and frequent and small pulse. 2 The phase of relative calm, characterized by muscle spasm and fever, during which the shock and pain gradually diminish. 3 The phase of spreading peritonitis, which appears rapidly, about the eighteenth hour. In acute appendicitis the symptomatology is milder. The pain begins in the epigastrium or the umbilical region, descends, and localizes itself in the right iliac fossa. The pain is neither sudden nor stabbing and does not, as in perforation, reach its maximum intensity from the beginning but increases constantly, reaching its acme after a few hours. The tongue is coated, the breath foul. The defense mechanism is less generalized and less intense. The author advocates early unilateral salpingectomy as the least traumatizing operation. It can be performed rapidly and it practically does not expose the pelvic cellular tissue to infection. Bilateral salpingectomy is performed when a salpingitis of the other side is also present. For most cases the author advocates unilateral or bilateral castration. Hysterectomy exposes the patient to too much infection. Drainage of the abdominal cavity is done with rubber tubes or with plain gauze strips.

Idem. G. Weber.—p. 93

Treatment of Dehydration in Nurslings.—Bratusch-Marrain considers the comparatively high water content of the tissues of nurslings as the main reason for the disturbances in the water economy so frequent during this age. In the dehydration that develops during pylorospasm, it is necessary to supply the circulation with sufficient amounts of water, but the water must be given either by rectum or by subcutaneous infusion, as oral administration is usually impossible. Conditions are much more complicated in the most severe forms of diarrheal disturbances, such as in intoxication. In this condition the dehydration cannot be overcome simply by the administration of water. The author advances the following theory to explain the peculiar conditions. In severe intestinal disturbances, toxins develop in the intestine, are resorbed and thus enter the circulation. They act particularly on the central nervous system and they have a general effect on the tissues, impairing their water binding capacity. Thus the tissues become dehydrated and the blood contains considerable amounts of free water (not bound to colloids). This water affects the respiratory center, as does increased carbon dioxide content, and causes intensified breathing, the so-called large respiration, by means of which the superfluous water is eliminated through the lungs. This theory of the pathogenesis of the large respiration and of the pulmonary elimination of water, which the author had advanced previously, contradicts the assumption that large respiration is caused by acidosis. In fact, recent experimental investigations have proved that acidosis does not exist and that even alkalosis may be present. The author's theory indicates that the dehydration in nursing intoxication can be counteracted only by treating the main disease, but in the meantime care should be taken that the organism has sufficient water to maintain the circulation and to eliminate the substances that are excreted with the urine. If fluid intake by mouth is impossible, subcutaneous infusion can be resorted to, but this treatment is only symptomatic because the dehydration cannot be counteracted as long as the toxic syndrome persists.

Treatment of Influenza with Amidopyrine.—Instead of the doses that are usually employed, Petrányi tried large doses. Nurslings of less than 3 months were given every two hours 0.05 Gm, those of from 3 to 6 months of age 0.1 Gm, those up to 1 year 0.15 Gm, and older children 0.2 Gm of amidopyrine until the fever subsided. This was usually the case after the third or fourth dose and undesirable complications did not develop. As soon as the temperature decreased to less than 37 C (98.6 F) and remained there for at least half a day, the intervals between the administrations were prolonged to three hours, then to four hours and after that the amidopyrine was given only three times a day, but when the fever returned, it was again administered more often. The amidopyrine was given in a 2 or 3 per cent solution with plenty of syrup. This method of treatment increases the daily dosage considerably compared to that which was formerly customary, since a nursing of 6 months receives at the beginning of the treatment 1.5 Gm daily. The author warns against a too rapid and too early decrease in the dosage. He also states that the best results are obtained if the treatment is begun early. The author states that these large doses of amidopyrine do not produce harmful effects, precaution being necessary only in weak and in tuberculous children. Other investigators have found that tuberculous fever yields more easily to amidopyrine than does the fever of other causes. Thus it can be understood that children who already react to smaller doses do not tolerate large doses so well. The author found that medication with large doses of amidopyrine had no harmful influence on the form elements of the blood or the hematopoietic system. The kidneys, renal pelvis and bladder were likewise free from impairments. But the author thinks that the parents of the children should be told that an acid disintegration product of amidopyrine colors the urine red. In the conclusion he points out that, with this method of treatment, nurslings and small children withstand an attack of influenza better because they lose less weight, the appetite improves, and fever and the other symptoms subside more rapidly. If the antipyretic action of amidopyrine fails, or the fever increases again after a temporary decrease, serious complications are liable to occur.

Osteochondritis Deformans Juvenilis Dorsi (Scheuermann's Disease).—Eckardt reports the case of a boy with a peculiar vertebral disorder. He relates the history and discusses the symptomatology of vertebral disorders that resemble the described case and from which it has to be differentiated, especially tuberculosis of the vertebral column. Scheuermann thought that, with the exception of its localization, this disorder is identical with Calve-Perthes disease, osteochondritis deformans juvenilis coxae. Both disorders develop during the period of growth and, while in osteochondritis coxae the disorder is localized in the epiphysis of the head of the femur, in Scheuermann's disease, that is, in the vertebral form, the process is localized in the growth line of the vertebrae, between the body and the epiphysis of the vertebrae. Schmorl maintains that the pathologic changes are found mainly on the marginal surfaces of the vertebral bodies and on the intervertebral disks, and that the changes on the epiphyses of the vertebral bodies are unessential. The author says that the case observed by him resembles most the disorder that Scheuermann designated as osteochondritis deformans juvenilis dorsi. The case has been under observation for eighteen months, and during this time the comparatively slight disturbances have not become exacerbated. The treatment consists of strengthening measures such as rest in the open air, cod liver oil, quartz lamp irradiation, prolonged bed rest and eventually the wearing of a support.

Endangitis Obliterans and Its Treatment.—On the basis of thirty cases of spontaneous obliterating endangitis observed in the Hamburg University surgical clinic, Rieder

reviews the debatable points in the pathogenesis, etiology and treatment of the condition. Nine relatively early amputations performed for pain and not for gangrene offered an opportunity for the study of the early stages of the morbid process. Thrombosis of the vessels of the thigh was observed in only two of the cases. The histologic process appeared to involve veins and arteries to the same degree. It consisted chiefly of a proliferation of connective tissue having its origin principally in the intima of the blood vessel, though other layers contributed to it as well. This proliferation was the cause of obliteration of the lumen of the vessel. The histologic observations, therefore, did not support Buerger's teaching of an infectious thrombosis being the initial process. Examination of the etiologic factors failed to bring out any one specific factor. All the patients were young or middle aged. The racial factor seemed unimportant, there being only one Jew in the series. The Ehrmann-Meltzer biologic pupil reaction test was negative in twelve out of fourteen tested cases, suggesting that the blood of these patients did not contain vessel-constricting substances. Thus Oppel's theory of hypersupranalemia as the cause of arterial spasms leading to gangrene in young persons received no support and the author could not substantiate Oppel's theory of hyperglycemia as a cause of juvenile gangrene. The condition appears to be one of the peripheral blood vessels rather than of an inner central origin. Some special constitutional predisposing factor must be added to the well recognized factors of chilling, trauma, infection, nicotine and fatigue. The clinical course may be insidious and last as long as twenty years. The ultimate fate of these extremities depends on the development of sufficient collateral circulation and recanalization of the obliterated vessel. The author had excellent results with the operation of sectioning the ram communicantes, or with the operation of a periarterial sympathectomy combined with the resection of the sympathetic ganglions. The operation is indicated in cases of thromboangiitis with threatened gangrene. The author obtained excellent results in seven of nine cases in which operation was thus performed. The pain was abolished at once, gangrene did not develop, amputations were obviated, and the patients remained symptom free for a number of years. No such effect was obtained in two cases. Attention is called to the possibility of spontaneous healing. The author is enthusiastic about the effect of periarterial sympathectomy when combined with resection of ganglions. The operation is successful in properly selected cases. The success of the operation can be predicted with certainty if there ensues a temporary relief from pain, hyperemia or hyperthermia on the induction of anesthesia of the nerves supplying the extremity.

Treatment of Diffuse Peritonitis—Peters gives a report on 581 cases of acute peritonitis from the service of Prof. G. Lotheissen during the period from 1920 to 1930. Of the patients, 306 were operated on or have died as the result of postoperative peritonitis. As in other statistics, the appendix constituted the principal cause. The author discusses the various methods of treatment, with especial reference to mortality, the formation of postoperative adhesions and the incidence of postoperative ileus. Kirschner's statistics demonstrated that flushing the peritoneal cavity or mopping out the exudate gave approximately the same result in cases of diffuse peritonitis, a mortality of 47 and 46 per cent, respectively. The author objects to the method of pouring ether into the peritoneal cavity on the ground that in several instances it had led to shock and collapse and to more frequent formation of adhesions. The author failed to note any good effect in the cases reported from flushing with physiologic solution of sodium chloride, ether, camphor in oil or peptohydrochloric acid solution (Eiselsberg). The objections to flushing are that it leads to undue exposure, eventration, wetting and chilling of the patient, that the bacteria cannot all be washed out, whereas the infection can be carried to uninfected parts, and that the bactericidal exudate and fibrin are washed out. The author favors a small incision, rapid removal of the focus of infection and careful peritonealization of the stump. Cleansing of the peritoneal cavity is accomplished by gentle, limited, dry mopping. Especial care is used not to traumatize the serosa, for fear of opening up to infection less resistant subserous layers. The author drains only in those cases in which an abscess is anticipated or in which the suture is placed in

phlegmonous tissues. In the postoperative treatment, Fowler's position, abundant supply of water and dry or wet heat to the abdomen were employed. No definite effect was observed from the use of gas bacillus antitoxin (Williams). Lumbar anesthesia gave good results when the bowels refused to move after the usual means, such as enemas and solution of pituitary, had been tried, otherwise an ileostomy was performed. The author divides the cases of peritonitis of appendicular origin into three groups: (1) severe local peritonitis with a clear exudate in the rest of the cavity, (2) encapsulated abscess with a more or less general reaction, and (3) diffuse general peritonitis. The mortality was 5, 54 and 28.5 per cent, respectively. The relatively low mortality was ascribed to the conservative method of treatment. Of the patients operated on, 62.7 per cent were followed up. 70.3 per cent were found to be symptom free, 12.6 per cent gave a history of symptoms referable to adhesions, such as gassy colics, pressure and abdominal pain, while 5 per cent developed intestinal obstruction. Adhesions developed in 34 per cent after diffuse peritonitis, in 15.4 per cent after a circumscribed peritonitis and in 8.3 per cent after abscess formation. The author concludes that limitation of drainage to the infected area did not lead to a higher incidence of postoperative adhesions than that obtained with the active treatment.

Tubercle Bacilli in Blood of Children—Siegl reports the results of parallel tests, on 140 children, that were performed in Löwenstein's laboratory and in the laboratory of Maresch. Some of the children had active tuberculosis, others had inactive tuberculosis, and the rest were free from demonstrable tuberculosis. The laboratory of Löwenstein reported positive results in 13.5 per cent of the children with active tuberculosis, 18.9 per cent of those with inactive tuberculosis, and 23.9 per cent of those with negative tuberculin test. In the two last mentioned groups there were many children with rheumatic disorders. In the laboratory of Maresch, tubercle bacilli were found only in the blood specimens of those children who had active tuberculosis, and even in this group the proportion of positive results was smaller than that reported by Löwenstein, as it was only 5.1 per cent. The Maresch laboratory never detected tubercle bacilli in the blood of children who had inactive tuberculosis or were entirely free from it. The animal test gave positive results only in one case, in a child with exudative pleurisy. The results of the tests on secretions and excretions of children with active tuberculosis showed about the same percentage of positive results, but the results of the various tests did not always correspond. In ten tuberculin negative children in whom Löwenstein's laboratory detected tubercle bacilli in the blood, the tuberculin test was repeated after the rheumatic symptoms had disappeared and, with the exception of one child who had been exposed to a tuberculous infection, all tests were again negative. Of eleven positive blood cultures in continuously tuberculin negative children, six could be tested in animal experiments and proved to be true tubercle bacilli. The occurrence of virulent tubercle bacilli in persons who are always tuberculin negative has not been explained as yet and, before this is attempted, it will be necessary to answer the question as to why the demonstration of tubercle bacilli in the blood

of tuberculin negative persons was possible so far only in Löwenstein's laboratory, while other laboratories, although they master the technic, have been able to detect tubercle bacilli only in the blood of patients with active tuberculosis

Phrenic Exeresis—Patronikola emphasizes that phrenic exeresis should not be overvalued. He thinks that the authors who recommend phrenic exeresis as an independent therapeutic intervention are misled by the improvement that sets in shortly after the operation. However, this improvement is generally only temporary, and the permanent results of phrenic exeresis are not favorable. Moreover, complications such as gastric disorders and milary tuberculosis may result in some instances. In answer to the question as to whether phrenic exeresis is to be recommended as an independent therapeutic measure, the author states that a material of 111 cases, which he studied for late results, revealed only 4 per cent of cures and 4 per cent of improvements. Consequently he does not recommend phrenic exeresis as an independent measure, as he thinks that approximately the same percentage may be accounted for by spontaneous recovery. Yet he points out that other measures likewise have sometimes only a temporary effect and that even temporary improvements are of some value. At any rate, phrenic exeresis should be tried as a palliative measure if several attempts to induce a pneumothorax have failed and the patient does not wish to undergo another surgical intervention. Phrenic exeresis is helpful as a palliative measure if adhesions exist between pleura and pericardium, but its effect is doubtful in pulmonary abscesses, bronchiectasis and pulmonary gangrene. Phrenic exeresis can also serve as an auxiliary operation, particularly in extrapleural thoracoplasty and in plugging of the lung. As a supplementary operation it is valuable particularly in empyemic cavities, and sometimes also in pneumothorax treatment. Phrenicotomy and not phrenic exeresis is justified in patients with a cavity near the hilus, as a measure to prevent serious hemorrhages.

Endocarditis Lenta During Childhood. E. Nedelmann—p 1880

Hypochloremic Uremia.—Hoff shows that the decrease in the blood chlorides and the increase in the alkali reserve which develop during normal acid secretion of the stomach are most pronounced in those cases in which frequent vomiting prevents a reabsorption of the chlorides secreted by the stomach. As a result of this uremic disturbances may develop because, during these severe changes in the mineral content of the blood, especially in pronounced hypochloremia the kidneys do not function properly and because there is an increased protein disintegration in the changed ionic milieu. In a man, aged 49, who had pyloric stenosis with frequent attacks of vomiting, coma developed following gastric irrigation. The sodium chloride content of the urine was almost zero, the chlorine content of the serum (normal 370) was reduced to 173.5 mg per hundred cubic centimeters, the alkali reserve was increased to 109 and the rest nitrogen was 122 mg per hundred cubic centimeters. Administration of sodium chloride increased the chlorine content of the serum to 274 mg per hundred cubic centimeters, and a gastro-enterostomy produced a slight temporary improvement but in spite of this the patient died in a coma. Examination of the kidneys at necropsy revealed only slight degenerative changes that could not be considered as the cause of the fatal outcome. In a case of mercury poisoning with severe vomiting, a combination of organic renal insufficiency and of hypochloremia was observed. The author describes several other cases of slight hypochloremia without uremia, some of which were complicated by gastric tetany. In his conclusion he emphasizes that the problem of a hypochloremic pathogenesis should always be investigated in uremic conditions since in these cases administration of large quantities of sodium chloride may save the life of the patient while in organic renal insufficiency sodium chloride administration is contraindicated. In cases of prolonged vomiting gastric irriga-

tion should never be done without control tests of the chlorine content of the blood.

Extracyclic Hemorrhages—Tietze classifies the disturbances causing extracyclic hemorrhages into two groups: (1) those caused by conditions connected with gestation, such as incomplete abortion, extra-uterine gravidity or endometritis after abortion and (2) those caused by malignant tumors, especially by carcinoma of the cervix uteri. The first group predominates before the menopause, the second group after the menopause.

Latent Infection and Epidemics—Friedemann calls attention to certain erroneous conceptions in the relation between latent infection, immunity and the development of epidemics. Why protect people against infection, if latent infection is so important for the immunity conditions in a population? The overcrowding of public transportation facilities ought to provide an ideal method to confer immunity on the people. The author emphasizes that this manner of reasoning disregards two important factors: (1) that immunization by means of natural infection is a double-edged sword, because one can never know whether the infection will remain latent or become manifest as disease, (2) that the course of an infection, besides being dependent on the susceptibility of the person, is also influenced by the quantity and virulence of the pathogenic agent. The author further points out that the beginning and cessation of epidemics constitute one of the most difficult problems in epidemiology. He cites observations and experiments from which he draws the conclusion that latent infection does not prevent the development of epidemics but even causes them, when persons without latent infection come into contact with persons with latent infections. Levinthal's theory of the origin of the influenza epidemic during the World War is cited in this connection. Levinthal assumes that it was caused by the importation of colonial soldiers who had no immunity against the pathogenic organisms of European influenza. In these troops the virulence of the organisms increased to such a degree that the immunity of the European population was not sufficient to protect against the outbreak of the infection and thus the terrible epidemic resulted.

Pathogenesis of Nursling Intoxication.—According to Rosenbaum the intoxication of nurslings usually begins with diarrhea, and then symptoms of the central nervous system develop in rapid succession. Delirious unrest is followed by coma, cataleptic rigidity, and twitching spasms, and high fever alternates with subnormal temperatures. Circulatory disturbances may develop and the respiration shows the peculiar, temporarily accelerated and then again retarded but always deep thoracic form that greatly resembles Kussmaul's great respiration. Everything seems to indicate some form of poisoning. Until recent years little was known about the pathogenesis, but recent studies have aimed to solve the following problems: the significance of the diarrhea, the nature of the toxin and the point of attack of the toxin. The diarrhea is significant in that it produces an exsiccosis, for there are cases of intoxication of nurslings which develop without preceding diarrhea but these usually begin with frequent vomiting, which likewise results in exsiccosis. Some authors assume an exsiccation of the portal region by protein as the most important factor in the pathogenesis of intoxication, but the author was able to show that there is no dehydration in the region of the liver. He further shows that the so-called protein fever is not identical with toxicosis of nurslings, but he does not deny that the pathogenic processes of protein fever and of toxicosis are related. The author discusses the nature of the causal toxin and reaches the conclusion that endotoxins of the coli

strains and perhaps also of related dysentery strains play a part in the pathogenesis. In regard to the point of attack of the toxin he states that a poisoning of the center of respiration seems probable, and he thinks that the entire central nervous system is involved. The treatment of the toxicosis should aim to overcome the exsiccosis, but administration of oxygen has also been found helpful.

Gastrocardiac Manifestations After Phrenic Exeresis—Induced by reports that phrenic exeresis is often followed by topographic, physical, pathophysiologic, pathologic-anatomic and functional changes in the heart apparatus, the gastrointestinal tract and the respiratory tract, Jahnke examined 232 patients who had undergone phrenic exeresis. He observed topographic displacements of organs, but these never led to severe gastric or cardiac disturbances. Many patients had complaints during the first few weeks after the intervention, but these gradually disappeared, and only in rare instances did the symptoms recur later, and were then, as a rule, only temporary. The author thinks that the somewhat more frequent dyspnea and cardiac manifestations are probably due partly to the reduced respiratory surface in destructive pulmonary processes, partly to the contraction of the thorax, and partly to changes in the lesser circulation, yet in view of the topographic and sometimes extreme organic changes, it is surprising how slight the manifestations are, as long as the cardiac muscle and the vascular system are healthy. The cardiovascular system adjusts itself to the changed condition in most instances. A slight circulatory insufficiency may persist in adipose types. Serious gastrocardiac conditions were never noted and the author concludes that hesitation in the employment of phrenic exeresis on this account is unfounded. At any rate the permanent or late impairments are so rare that they may be disregarded in the selection of the cases for phrenic exeresis.

Glycogen Disease—Unshelm gives a detailed description of the clinical histories of two children (brothers) who had a congenital disturbance of the carbohydrate metabolism. The diagnosis was at first difficult, but then the author found that von Gierke had described cases with this symptomatology and had designated the disease as hepatonephromegalia glycogenica. The most noticeable symptom is an abdominal distention that is either congenital or develops during the early months of life. The cause of the large abdomen is an enormously enlarged liver, which is firm and smooth and has a high glycogen content. In the cases described by von Gierke the kidneys were likewise enlarged and rich in glycogen. At birth the children are usually of normal size, but the later development shows a considerable retardation. The bony structure is usually abnormally fine and, in one of the cases described, the thin legs are in great contrast to the other parts of the body, in which the subcutaneous fat layer is well developed. The hairy covering of the body shows abnormalities, either a falling of the hair or, as in the cases observed by the author, a persistence of lanugo. The abnormalities of the blood consist of a hemorrhagic tendency and a hypochromic or hyperchromic anemia, in one of the children there was poikilocytosis and anisocytosis. The leukocyte numbers are more or less normal, but the lymphocytes are relatively increased. Constipation is reported in the author's cases, but in one of them thin stools were occasionally noticed. The urine may be free from pathologic constituents but, in one of the children, acetone was found in the morning urine and, after eating, the urine contained sugar. Von Gierke observed an enormous increase in the glycogen content of the blood. Whether the increase in inorganic phosphorus is due to the disturbance in the sugar metabolism or to a rachitic disturbance cannot be definitely decided. In regard to the diastase, the author states that the increased elimination in the urine is of little differential diagnostic value, because the tests

were made at the end of the winter, but he considers the irregularity in the diastase elimination and the high diastase content of the blood a peculiarity of the glycogen disease. He further shows that the glycogen disease has to be differentiated from a number of disturbances in which an enlargement of the liver exists, particularly from hypertrophic cirrhosis, because not a single symptom of glycogen disease is so characteristic that a definite diagnosis can be based on it.

Sinus Thrombosis Following Intoxication—In the necropsies of two cases of alimentary intoxication of noninfectious origin, Wüst found sinus thromboses in the sagittal sinus, sigmoid sinus, longitudinal sinus and the sinuses of the base of the brain, while other veins were free from thromboses. This gives rise to the question why the cerebral sinuses are the sites of predilection. The author thinks that fluctuations in the pressure of the cerebral fluid, which in turn influence the sinuses, are probably significant, and that the resulting change in the current velocity of the blood may give an explanation for the localization of the thromboses.

Basal Metabolism and Perspiratio Insensibilis—Jores gives a tabular report of 105 cases, in which he compares the results of the basal metabolism test with those of the determination of the perspiratio insensibilis. He shows why several other investigators of this problem obtained results that differed so widely from those forecast by Benedict-Root. In regard to the question as to whether the measurement of the perspiratio insensibilis could serve as a metabolism test, he states that the gas metabolism test is a reliable method, so that its replacement by a new method would be justified only because of greater exactness or a simpler method. These two requirements are not fulfilled in the measurement of perspiratio insensibilis, because its results are the same as those of the gas metabolism test in normal persons and are less exact in metabolic disorders, and the technic is not simpler. The author thinks that the determination of the perspiratio insensibilis, at the most, can be a substitute for the gas metabolism test in cases in which the latter cannot be employed on account of resistance on the part of the patient, for the determination of the perspiratio insensibilis does not exert the patient.

Suprarenal Cortex and Myasthenia Gravis Pseudoparalytica—Bernhardt and Simpson state that, in the treatment of six patients with Addison's disease, they obtained the same good results with the new hormonal extract of the suprarenals as were first reported by American authors. They point out that, because the suprarenals are of great significance in the endocrine and sympathetic processes of the organism, the new suprarenal extract has been tried also in various other disorders. A favorable action of the extract has been observed in hyperthyroidism, postdiphtheric asthenia, hyperemesis gravidarum and conditions of fatigue and weakness. The efficacy of the extract in counteracting fatigue was an inducement to try it in myasthenia gravis pseudoparalytica, the pathogenesis of which remains still unexplained, although many assume endocrinal disturbances, particularly of two glands, the thymus and the suprarenals. In two patients with severe myasthenia, the suprarenal extract was tried but proved ineffective, and therefore it seems improbable that the suprarenals play a part in the pathogenesis. It was observed that the cholesterol content of the blood was considerably affected by the hormone, whereas the blood pressure and the sugar and calcium content remained unchanged. Attempts to influence myasthenia gravis pseudoparalytica with subcutaneous injection of small doses of epinephrine and pilocarpine, a treatment that had been recommended for muscular dystrophy, failed likewise, but one of the two case reports shows that irradiation of the region of the thymus was followed by considerable improvement.

Hippus in Multiple Sclerosis.—Twenty years of observations convinced Herzog that hippus, spasmodic alteration of the size of the pupil, is a frequent symptom of multiple sclerosis. It has diagnostic value because it is observable in the incipient stages in which there is usually a deficiency of symptoms, and it is frequently the only cerebral symptom. However, the tremor is sometimes intermittent, that is, it may be absent for several seconds, and the author thinks that this is the reason some other investigators have overlooked the symptom in patients with multiple sclerosis, because one glance at the size and shape of the pupils may not reveal this form of hippus. He admits that spasmodic alteration of the size of the pupil occurs also in a number of other disorders, but his version of the mechanism of the development of hippus makes it appear likely that in multiple sclerosis it occurs more often than in any other disorder.

 Morphologic and Functional Relations Between Fetal Elements and Walls of Uterine Tubes During Gravidity. A. Terechowa—p 66
 *Amenorrheal Syndrome. G. H. Schneider—p 83

Significance of Different Forms of Calcium.—Spiegler states that calcium occurs in the blood in three forms, as ionized calcium, in salt form and as a colloidal protein compound. It is of great importance for the calcium metabolism whether the one or the other form predominates, and it is evident that research on calcium metabolism could make little progress until, in addition to the total calcium content, the various forms in which calcium occurs were given consideration. The author reports a case of tetany in which, under the influence of treatment with parathyroid extract, interesting changes were noted in the proportions of the various forms of calcium. Colloidal calcium was not demonstrable before the treatment was begun, but after administration of parathyroid extract the colloidal calcium amounted to 27 per cent of the total and the calcium in salt form had increased whereas the ultrafiltrable calcium had decreased to less than half of its former percentage. The total calcium content was somewhat increased but was still subnormal. These observations indicate that the calcium content of the blood is not as stable as had been assumed as long as only the total content had been considered, but that it is extraordinarily labile because tests revealed that the administration of parathyroid extract may produce a complete reversion in the percentage of the different forms of calcium within the short period of only two hours. It is the possibility of such sudden changes is taken into consideration it seems no longer surprising that for instance, eclampsia suddenly develops without preceding clinical symptoms.

Amenorrheal Syndromes.—According to Schneider, amenorrheal syndromes are of uterine ovarian or hypophyseal origin. He thinks that it can no longer be doubted that the central regulation of ovulation is located in the hypophysis, particularly its anterior lobe, and in the related centers in the central gray matter on the floor of the third ventricle. The motor impulses of a primary hypophyseal cycle produce a

secondary ovarian cycle and this, in turn, causes the cyclic changes in the uterine mucous membrane. Unless it is possible to find an isolated cause, the therapy of amenorrhea should influence both the hypophysis and the ovaries. A substituting organ therapy combined with roentgen treatment gives good results.

Acute Articular Rheumatism.—Singer calls attention to the significance of infections of the pharyngeal organs, which are considered as the most frequent port of entry of acute infectious arthritis. He points out that the causal significance of infections of the tonsils, particularly of streptococcal tonsillitis, had been recognized by some investigators several decades ago. Later it was assumed that other infections, such as those of the accessory sinuses, or certain forms of otitis or alveolar pyorrhea may also have a pathogenic significance. Although the beginning with acute infections is the most frequent, there are also cases in which the articular manifestations are preceded by a feverish systemic disorder. After discussing the opinions of different investigators on fever in rheumatic conditions, the author directs attention to the nervous and dermatologic (erythema multiforme) symptoms that frequently develop during the initial stage of articular disturbances, but he considers the cardiac manifestations as the most important sign of the infectious character of acute rheumatism. He emphasizes that *Streptococcus viridans*, which was considered as the specific organism of endocarditis, is also the cause of the rheumatic infection, and he is convinced that the cardiac manifestations are the most significant ones in the course of the rheumatic infection and that in some instances they may be the first manifestation of the rheumatic process. The nodules first described by Aschoff are products of tissue transformation which may be produced by different tissue impairing influences. Although streptococci have been detected in such nodules, these are now generally considered as the sign of a changed reaction (allergy), but those authors who adhere to the allergic theory have to accept bacterial proteins as the causal factor, and nearly all again fall back on the streptococci. In his conclusion the author emphasizes once more that the infectious agent enters the blood stream and thus causes the clinical manifestations, particularly on the most important circulatory organ, the heart.

Health Impairment by Slight Noises.—Pinoff shows that no matter whether a steady noise fatigues the acoustic nerve so strongly and persistently that the noise is no longer heard, or whether it is suppressed in consciousness because it disturbs, it is detrimental to the health. In the first case, the fatigue of the nerve implies a fatigue of the entire nervous system, which impairs working capacity in that one has to expend energy in order to overcome it. In the second case, an effort has to be made to eliminate it from one's consciousness. The author thinks that in many instances nervousness may be due to the influence of noises, for even slight noises are injurious if they persist.

 *Treatment of Menstrual Disturbances. J. Novak—p 1512

Static Lumbago.—Saxl points out that the burdening of the vertebral column becomes manifest primarily in the lowest of the movable vertebrae, that is, in the fifth lumbar vertebra.

The articular connection of this vertebra with the sacrum, owing to the obliquely inclined position toward the front and downward of the fifth lumbar vertebra, is taxed most heavily. A disparity between work requirements and functional capacity may therefore readily lead to impairments. The reduction in the functional capacity, characterized by fatigue and by static lumbago, may be relative or absolute. It is relative if the requirements of the lumbosacral portion of the vertebral column, in regard to burdening as well as in regard to movement, are extraordinarily great, it is absolute if congenital or acquired defects of the lumbosacral joint impair its normal functional capacity. Static lumbago is due to overextension, loosening and straining in the connection of the fifth lumbar vertebra with the sacrum, and, if the functional requirements are great, these conditions may acquire an inflammatory character, particularly if, as the result of bone defects, the position of the fifth lumbar vertebra has been changed. Simple static lumbago may occasionally cause pains that spread to the flanks, also sensitivity in the lumbosacral articulation and articular pain during maximal bending, but movements toward the side do not cause pain. The erector spinae does not show fixation or pressure sensitivity in this mild form of static lumbago. In severe cases, particularly those leading to arthritis, the mobility is impaired, the region of the joint is sensitive to pressure, and the erector spinae shows spastic fixation. The treatment of static lumbago should aim at an improvement in the functional capacity of the joint by mechanical measures, but a weak joint should be given support by suitable appliances. In rare cases an operative intervention may be required. Physical therapy is advisable in cases in which inflammation causes an exacerbation of the static lumbago.

Treatment of Menstrual Disturbances—Novak discusses the treatment of amenorrhea. He points out that the physical measures that are frequently employed, such as diathermy, hot foot or sitz baths, moor or mud packs, mustard baths and poultices, all have the object to produce genital hyperemia. Change in the milieu, particularly sojourn at altitudes between 700 and 1,100 meters, is also helpful in some cases of amenorrhea. In discussing emmenagogues the author mentions iron, arsenic and particularly potassium permanganate, but also certain vegetable products. The treatment with sex hormones, particularly folliculin, should aim at imitating the normal cyclic change in the hormonal content of the blood, that is, because the hormone content of the blood increases steadily from the time of menstruation until it reaches the maximum shortly before the next menstruation, the dosage of the hormonal preparations should be gradually increased and then discontinued several days before menstruation. During the third and fourth week, administration of a standardized corpus luteum preparation should be combined with the folliculin medication, but this should likewise be discontinued a few days before menstruation. The hypophyseal hormone preparations have not come up to expectation, but it sometimes proves helpful to combine roentgen irradiation of the hypophysis with the administration of sex hormones. The abnormally profuse or the too frequent menstrual hemorrhages usually yield more readily to treatment than does amenorrhea. It is generally possible to check the hemorrhage by preparations producing contraction of the vascular or uterine musculature. Corpus luteum preparations are helpful in cases of menorrhagia due to small cystic degeneration of the ovaries. A preparation of the posterior hypophysis and autohemotherapy have also proved effective in some disorders of menstruation. An operative intervention becomes rarely necessary, and before resorting to it roentgen treatment may be tried. Occasionally an irradiation of the liver or spleen checks or at least reduces the hemorrhage and, if this is not the case, ovarian irradiation can be attempted, but this requires precaution because it involves great dangers. The author further discusses the treatment of the menstrual pain, particularly the form designated menstrual colic by him. He believes that it is due to a spastic contraction of the smooth muscles of the internal genitalia. It was produced first by a severe shock, and the fear of the return of the pain produces it again and again. This pain can be overcome in many instances by a psychoanalytic method, namely, discovering the psychic trauma that caused the first attack and explaining the pathogenesis to the patient. The great number of antispasmodic medicaments that have been recommended indicates that not

one of them is entirely reliable. Treatments based on the supposition that the menstrual pain is due to mechanical obstruction of the discharge are rarely effective.

Blood Transfusion in Dermatology—Scherber relates his experiences with blood transfusion in cases of severe burns and agranulocytosis. He reports the effects of blood transfusion in impetigo herpetiformis, in which it proved life saving. In pemphigus vulgaris it was valuable as an adjuvant. Blood transfusion failed in two cases of the mildest form of pemphigus vulgaris, in dermatitis multiformis, in which the improvement was only temporary, and in a case of pemphigus acutus malignus. Blood transfusion effected a remission in a case of relapsing aphthous stomatitis, but there was a new relapse after several weeks. The author recommends blood transfusion in the severe forms of acute and chronic purpura, particularly in purpura hemorrhagica, and he states that severe cases of erythema multiforme can be effectively treated by combining acetarsone treatment with blood transfusion. Exceptionally favorable results can be obtained by blood transfusion in severe forms of metal poisoning, such as in dermatitis arsenicalis after arsphenamine medication and in gold dermatitis, while the milder forms of these disturbances generally yield to baths, sulphur ointments and sodium thiosulphate. Because favorable results were obtained with blood transfusion in septic erysipelas, in sepsis following furunculosis and in sepsis during severe gangrene of the mouth, the author recommends it for such cases and also for cases of gonococcal sepsis. In the conclusion he discusses the action mechanism of blood transfusion.

Roffo's Cancer Reaction—Gandolfo states that the reaction was discovered by Roffo in 1925, in the course of experiments with the serums of normal and tumor-bearing rats. Subsequently the test was studied by a number of other investigators. With few exceptions, all of them corroborated Roffo's observations. Following a review of the literature, the author gives a statistical report of the results of Roffo's cancer reaction in 11,000 cases, in 4,282 cancer patients and in 6,718 patients with other diseases. On the basis of these, he concludes that a negative Roffo reaction does not definitely exclude the presence of a tumor but, in case of a positive reaction, the search for a neoplasm should be continued, because the proportion of erroneous positive results is slight (6.37 per cent). The highest percentage of positive reactions is obtained in cancers of the internal organs, and this makes the reaction the more valuable since the clinical diagnosis of these cases is especially difficult. The author thinks that the value of the reaction as a diagnostic aid, and the simplicity of its technic, recommend it for use in the clinic.

Acute Urticarious Toxic Exanthem with Necrosis—Scharman reports that a gravida with eclampsia developed an acute urticarious toxic exanthem three days before delivery. The itching was slight, there were no gastro-intestinal disturbances, and an exogenous cause could not be detected. Following an attack of eclampsia, the exanthem became exacerbated. It disappeared immediately after delivery but left scars of the size of the hemorrhages. An examination of the blood before

delivery revealed a considerable increase in the rest nitrogen (56.38 mg per hundred cubic centimeters), but forty-eight hours after delivery the rest nitrogen had decreased to 36.12 mg per hundred cubic centimeters.

Treatment of Suppurative Wounds with Hypertonic Solutions—Pankratiew and Poltow obtained good results with 25 per cent aqueous solutions of magnesium sulphate and sodium sulphate in the treatment of abscesses, phlegmons, mastitis and large carbuncles in which a wide opening by incision and, eventually, the introduction of a tampon is necessary. In furuncles and in small carbuncles, instead of making an incision, they lift off the ripe top with small pincers and then use the hypertonic solutions. Suppurating wounds resulting from injuries, frozen limbs and burns can likewise be treated with the solutions. In all cases in which this treatment is employed, the pains disappear rapidly, the temperature becomes normal, and the time required for healing is considerably shortened. Magnesium sulphate gives somewhat better results than sodium sulphate in that it counteracts the pain more successfully. Wide application of the treatment with these hypertonic solutions is justified not only because the method gives good results but also because it is simple and inexpensive.

New Methods of Flocculation Reactions—Kiss rejects the widely accepted opinion that the chemical nature of the extracts used in syphilis reactions is of no importance. The untenability of this assumption becomes evident when proof is brought that chemically definable substances such as lecithin and cephalin can be used as antigens. It is the lecithin and cephalin of the heart extracts that undergo physical changes under the influence of syphilitic serums. Phosphatide solutions (lecithin plus cephalin) are the stock solutions for the preparation of antigens for the various flocculation and conglobation reactions. The addition of cholesterol increases the flocculation tendency of the antigen solution. However the reactions can be done also without cholesterol which shows that cholesterol is not an essential constituent of the specifically active antigens. Depending on the method of preparation one obtains from the phosphatide solution an antigen solution in which either the lecithin or the cephalin properties predominate. It is characteristic for lecithin that it reacts with serum only after previous heating, whereas cephalin reacts also with unheated serum. The specific susceptibility of the antigen solution is dependent on the degree of dispersion for a finely dispersed solution is not suitable for practical purposes. The author thinks that antigens of known chemical composition should be given the preference in serologic tests and that antigen solution should always be tested for its physical properties. The high alcohol content of the concentrated lipid suspensions is the cause of their lability and it has been found that alcohol-free suspensions are stable and can be preserved for several days. A flocculation reaction has the highest degree of intensity when a concentrated

antigen solution reacts with the serum in a small volume of mixture. The possibility of employing photometry in flocculation reactions is limited for the reason that photometric measurements are successful only in finely dispersed solutions. The author describes a new technic for a conglobation reaction, the cephalin conglobation. Unheated serum is mixed with a small amount of concentrated, entirely precipitated lipid suspension that is rich in cephalin. This mixture is strongly diluted with a 0.5 per cent solution of sodium chloride and, after heating to from 52 to 58 C, it is placed in a cool water-bath, in which the conglobation develops after twenty minutes. The conglobation reaction that is produced with a reagent rich in cholesterol and with an inactivated serum is a combination of flocculation and conglobation.

Modification of Citochol Reaction.—Schirwindt states that the new modification of the citochol reaction has the advantages that it employs a relatively less coarsely dispersed dilution of homogenic extract than does the old citochol reaction or the Kahn reaction, that the pipetting of the ingredients is easier and more exact, that the consumption of extract is more economical and that it has a high degree of sensitivity. From the theoretical aspect, the modification is interesting in that the dilution of the cholesterolized extract is done by two successive dilutions of the stock extract with a concentrated sodium chloride solution. The author advises against the use of a 0.9 per cent solution of sodium chloride for the dilution of the stock extracts, because it results in a high percentage of erroneous reactions. As the best means of dilution of extracts he recommends a 3 per cent solution. In order to test the practical value of the modification of the citochol reaction, the author made comparative tests with the old and new citochol reaction and also with the Wassermann and Kahn tests on 1,219 serums. On the basis of these tests, he reaches the conclusion that the new modification of the citochol reaction is a valuable supplement to the existing methods for the rapid serodiagnosis of syphilis. In sensitivity it surpasses the three methods with which it was compared. This was noted especially in latent syphilis and also in experimental syphilis of rabbits.

Granulosa-Cell Tumors—Fauvet states that granulosa-cell tumors of the ovary have been known for the past forty years but that their histogenesis was clearly established only during the last decade through the teaching of Robert Meyer and his school. These tumors originate from the granulosa layer of the ovary. They have thus far been found to grow unilaterally and to possess a definite and rather thick capsule which as a rule, remains intact. Both metastases and recurrences are rare. The histologic picture is fairly typical. Clinical diagnosis of the character of the tumor is sometimes suggested by the appearance of certain functional symptoms. These tumors provoke an abnormal increase in the formation of the female sex hormone, with the resulting "feminization" of the patient. Hypertrophy and hyperplasia of the myometrium, the endometrium and occasionally of the breasts takes place. Endometrial hypertrophy rather commonly leads to uterine hemorrhages which constitute the most important clinical sign. In spite of sex stimulation these patients do not exhibit an effect of rejuvenation, to the contrary, they are sick persons. The relationship of the sex hormone to the secretion of the anterior lobe of the pituitary was established in one case. The possibility in the future of establishing the nature of the tumor by means of testing the presence of abnormal hormones in the blood is suggested. Among seventy-six cases of ovarian carcinoma observed in the Leipzig University clinic between the years 1928 and 1931 there were found eight cases of granulosa-cell tumors an incidence of 10 per cent. The prognosis is relatively good, even in the rather exceptional instances of metastases.

- *Effect of Acute Infection on Function of Reticulo-Endothelial System. I M Neiman —p 543

Hypoglycemic Hormone of Suprarenal Gland—Medvedeva, in a series of previously reported experiments, demonstrated that the suprarenal cortex contained a substance which, when injected subcutaneously, exhibited a distinct hypoglycemic effect. The maximum effect was noted from two and a half to three and a half hours after the injection. The blood sugar diminished until only traces were left, in some cases to the point of total disappearance from the blood. The action of the hormone did not apparently depend on insulin, since it was effective in diabetic dogs as well. To determine the specificity of the hormone, to which the author wishes to apply the name "corticaline," the effect of various other tissue extracts were tried. Extracts were prepared by the same method from muscles, lungs, liver, pancreas, intestine, stomach and lymph nodes. Blood sugar determinations were made every half hour for four hours. None of the organs mentioned proved to possess an active principle capable of reducing the blood sugar. Muscle extracts were demonstrated to possess a distinctive hyperglycemic effect. These results support the author's belief in the specificity of corticaline as an active hypoglycemic hormone of the suprarenal cortex.

Acute Infection and the Reticulo-Endothelial System—Nieman injected 1 cc of a 0.05 per cent solution of trypan blue two or three times into the peritoneal cavities of white rats. This was followed by a bluish discoloration of the skin and the visible mucous membranes. The color gradually faded but was still present at the end of three months. At the end of this time the author made an incision in the skin of the back of the animals, laid a gauze sponge into it and secured it there with a suture. When, nine days later, the suture was removed and the gauze sponge was examined, it was found to be saturated with secretion and to be colored blue. At the same time it was noted that the bluish discoloration of the skin and mucous membranes began to fade. It thus appears that the colloidal particles of the dye, lodged in the cells of the reticulo-endothelial system for some time, were now transported to the seat of acute inflammation. The intensity of this process was such as to decrease materially the general discoloration of the skin and mucous membranes. The "blocking" of the system was thus cleared and its functional activity raised. The author suggests that infections terminating favorably may play a part in the stimulation of the functional activity of the reticulo-endothelial system.

Acute Infectious Inflammation in Inner Ear—Blomroos reports forty-six cases of acute diffuse suppurative labyrinthitis treated from 1919 to date, in all but two of which labyrinthectomy was done. Of the sixteen cases of acute otitis with labyrinthitis, fourteen of which showed a fully developed meningitis before resection, eleven, or 68.75 per cent, were fatal. He says that in otitis with acute diffuse labyrinthitis tending to rapid aggravation, operative treatment must not be delayed. Of the nine cases of chronic otitis with labyrinthitis and fully developed meningitis on admission, six, or 66.7 per cent, were fatal. Such cases call for operation at once and resection of the labyrinth. Of the fifteen cases of chronic otitis and acute labyrinthitis but not meningitis on admission, with meningitis appearing after admission in seven, twelve, or 80 per cent,

recovered. In these cases immediate lumbar puncture is advocated. If the cell content of the lumbar fluid is not abnormal, absolute quiet is ordained. If on repeated puncture within a few hours the cell count is definitely rising, immediate labyrinthectomy is urged. If, on the other hand, the labyrinth symptoms recede, possible operation is deferred until the acute stage subsides. Of the six cases in which labyrinthitis set in shortly after radical operation, three were fatal. Extreme care in radical operation in cases of fistula toward the labyrinth is considered the most effective means of avoiding these labyrinthitides.

Action of Embryonal Extract on Speed of Wound Healing—Sandelin and af Björkstén found that, in experimental animals treated with embryonal extract, wounds healed 20 per cent more rapidly than in the untreated control animals.

- Tribrom Ethanol Anesthesia J M Wollesen —p 1375

Diastasia in Diseases of Biliary Tract—Foged made 1,500 analyses of the diastasia in 310 patients with gallbladder calculi or inflammation of the gallbladder. A pathologic diastasia was seen in about 15 per cent of the cases of inflammation of the gallbladder and uncomplicated gallbladder calculi, and in about 60 per cent of the cases of stone in the common bile duct. The symptom is ascribed to an irritation of the pancreas through the process in the biliary tract, in cases of stone in the common bile duct there is usually a retention of secretion, he says, due to obstruction in Vater's papilla. Pathologic diastasia is considered important in the differential diagnosis between common bile duct stones with jaundice and hepatitis and cancer of the head of the pancreas, an increased diastasia in cases of suspected stone in the ductus choledochus supporting this diagnosis, although the absence of pathologic diastasia does not testify against the diagnosis. A pathologic diastasia was found in 23 per cent of sixty-nine patients after intervention on the biliary tract, but not more often in cases of stone in the common bile duct than in uncomplicated gallbladder calculi.

THE USE OF LIVER EXTRACT INTRA- VENOUSLY IN THE TREATMENT OF PERNICIOUS ANEMIA

RAPHAEL ISAACS, M D
CYRUS C STURGIS, M D
S MILTON GOLDHAMER, M D
AND
FRANK H BETHELL, M D
ANN ARBOR, MICH

Following the demonstration in 1928 by Beckmann¹ and in 1929 by Cohn, McMeekin and Minot² that liver extract could be given intravenously to patients with pernicious anemia with good therapeutic results, numerous forms of the material have been used with success. The first published formula of a simply prepared product was that of Castle and Taylor³ in 1931. Their solution consisted essentially of liver extract No 343 N N R washed with ether and dissolved in physiologic solution of sodium chloride. A later modification (Strauss, Taylor and Castle⁴) was made by using an aqueous solution at a pH of 7.4.

Intensive studies of the blood changes following the intravenous use of Castle and Taylor's solution were made in our laboratories in May, 1931, and were reported in November, 1931.⁵ As the reactions following this treatment were too severe to make the medicine of routine clinical value, it was necessary to prepare a purified form. The fall in blood pressure, flushing of the face and other symptoms, described later, suggested the presence of extraneous substances of the nature of histamine, choline or guanidine. As these materials can be removed from solution by passing them through permutite,⁶ a method based on this principle was devised.

Although we have developed several modifications in the method of making the liver extract the following

is satisfactory. Several stages in the development are described, as many observations were taken with the use of material made by each method.

FORMULA A

Commercial liver extract (e g, Eli Lilly & Co's No 343 or Liver Extract-Parke, Davis & Co) is dissolved in water, 3 Gm in 100 cc. The solution is boiled for three minutes, filtered and cooled. It is then passed slowly through a column of freshly neutralized, washed permutite (Folin), 25 cm in length and 25 cc in volume. The solution is then filtered and sterilized by boiling or by heating to 80 C on three successive days. Instead of using the commercial liver extract powder, an aqueous extract may be made of whole liver, boiled, filtered, treated with 70 per cent alcohol and the filtrate from this employed for the permutite extraction.

Liver extract made from formula A was used for 626 injections in 106 patients. In 359 injections in 65 patients (1 to 19 injections) no reaction was noted. In 41 other patients given 267 injections, 97 reactions were noted as follows: Forty-one patients had one or more reactions, 21 had two or more reactions, 13 had three or more, 10 had four or more, 5 had five or more, 4 had six or more, 2 had seven or more, 1 patient had eight reactions. This last patient did not react every time, showing no reaction on seven other occasions.

FORMULA B

While it was evident that some patients never showed a reaction, there was still some substance present which affected certain individuals. It was found that this could be removed by adding acetone to the aqueous liver extract solution to the concentration of 70 per cent. After heating in a reflux condenser for fifteen minutes and centrifugating off the insoluble part, the acetone was distilled off at 50 C under reduced pressure, and the liver extract solution, brought back to the proper volume with water, was passed through the permutite, filtered and sterilized. With formula B no reactions, other than flushing of the face, have been noted in any of the patients (150 injections), even those who previously had reacted frequently. This extract is a deep yellow and has a reaction of about pH 4.4.

METHOD OF GIVING INJECTIONS

The present paper is a review of 1,000 injections given to 140 separate patients with pernicious anemia. The injections were given at the rate of 20 cc in from one-half minute to twenty minutes, with the patient lying down. The newer preparation (B) can be given at the more rapid rate although it is probably advisable to give the injection in about five minutes. Blood pres-

For purposes of ease of manipulation, a 20 cc dose was selected as the most feasible, when slowness of administration is important. This type of extract may be given in from 2 to 5 cc doses intramuscularly. The most convenient dosage by the intravenous method was found to be 20 cc once a week until the blood count reached normal, then once every month. While this is the average dose, some patients may require more. The criterion of dosage is to give a sufficient quantity to keep the number of red blood cells within normal limits.

Table 1 shows the effects of the intravenous method of treatment on thirty-nine patients whose initial red blood cell counts were low enough to be followed by an appreciable reticulocyte increase during the first week of therapy. A mathematical study of the data, for use as standards for testing the potency of different preparations, is being published from this laboratory by Drs Goldhamer and Bethell.

EFFECT OF UNREFINED LIVER EXTRACT ON THE BLOOD PRESSURE

The effect of commercial liver extract (for oral use) dissolved in physiologic solution of sodium chloride, either directly or after first washing with ether as suggested by Castle and Taylor,³ when given intravenously, was studied on several patients. The first subjective sensation is a feeling of warmth, followed by a sinking sensation in the abdomen, sometimes a cramplike pain. This is temporary and is followed in some by a sensation of choking, air hunger, nausea, a peculiar feeling in the chest and pounding of the heart

Some complain of a tight feeling over the body or a tingling sensation in the toes and fingers. Objectively there is a flushing of the face, occasionally vomiting, perspiration and rapid respiration. The systolic and diastolic blood pressures fall rapidly, in one patient from 120 systolic, 80 diastolic to 90 systolic, 50 diastolic, within from 3 to 120 minutes. This may last from sixty minutes to forty-eight hours. A second fall in the blood pressure may be noted after from six to eight hours (chart 1). About forty-five minutes after the injection is finished a chill may start, and this may last from fifteen minutes to one hour. It varies in intensity from a chilly sensation to the most violent type of shaking. With this there is a rise in temperature to a maximum of 104 for from two to four hours. After the injection the urine becomes dark, owing to the excretion of pigment or nonabsorbed liver extract.

While the powdered liver extract from one commercial company caused a fall in blood pressure when dissolved in water and given intravenously, the material from another company caused a marked rise in the pressure accompanied by a headache, which in some cases was unbearable. This type of extract was made and divided into two portions. The one was left unchanged and the other was passed through permutite. The first portion was given to a patient, but the injection had to be stopped because of the intense pain in his head. The systolic pressure rose from 112 to 145. The headache subsided after about fifteen minutes, and then the permutite treated solution was given. There was no pain or reaction, although the blood pressure, which had fallen, rose once more to the high level for a few minutes. After this it rapidly returned to the pretreatment level (chart 2).

SUBJECTIVE SENSATIONS WITH PURIFIED LIVER EXTRACT

With the purified liver extract there are usually no subjective changes, although there may be a slight flushing of the face or a "sinking sensation" in the

Chart 1—Effect of an aqueous solution of liver extract 343 A N R on the blood pressure and the chill and febrile response after intravenous injection

abdomen. When properly made, the liver extract seldom causes even these changes. There is no fall in blood pressure and no chill or elevation in temperature. Some patients, however, appear susceptible and will have a typical reaction when a preparation (e.g., formula A) is given that caused no reaction in other

individuals. Some of the patients received nineteen injections with no reactions, whereas twenty-one of the patients receiving the extract made according to the formula described showed reactions on two or more occasions. While speed of injection may have been a factor (Hirschfeld, Hyman and Wanger⁷), some other cause must be sought to account for most of the reactions. With the liver extract made according to the last formula (formula B, 70 per cent acetone-permutite) no reactions of any kind

have been noted, except flushing of the face, in 150 injections. There have been no local reactions at the point of injection, and no pain, sloughing or thrombosis have been noted. The clinical improvement has been marked and rapid in all patients who received an adequate dose of a potent material.

THE RETICULOCYTE RESPONSE

With the intravenous liver extract, the reticulocytes start to increase in number in from 12 to 24 hours, and reach their maximum percentage in from 68 to 108 hours. They decrease to less than 3 per cent in

Chart 2—Effect of liver extract in intravenously before (injection 1) and after (injection 2) filtering through permutite. Injection 1 had to be stopped because of the headache. Injection 2 did not cause any pain.

264 hours. A detailed study of short interval changes in the blood count of these patients is being published by Drs Goldhamer, Isaacs and Sturgis, from this laboratory. Compared to the maximum reticulocyte percentage reached with six vials daily of a potent liver extract by mouth, the total of the average maximums was over two-fifths higher than the total of the averages calculated for this series. This is interesting when it is remembered that the response here is the result of giving liver extract made from about 125 Gm of fresh liver as compared with that from 4,200 to 4,800 Gm by the oral method. It is more comparable to the response obtained when massive doses of liver extract were given by mouth (Riddle and Sturgis⁸).

It is evident that much of the active substance is destroyed or not absorbed when the extract is taken by mouth. The intravenous route, which simulates the normal pathway of internal secretions of the liver to the body, supplies the bone marrow with a greater amount of the active material, and the maturation of the red blood cells is facilitated in larger quantities at one time.

INCREASE IN RED BLOOD CELL COUNT

In a group of eight patients whose average initial red blood cell count was 0.84 million per cubic millimeter (0.75 to 0.98), it required 63.9 days (34 to 100) to reach an average count of 4.35 million per cubic

millimeter (3.97 to 4.89). The average gain per week was 0.391 million per cubic millimeter for the whole period from the initial count to four million or more. The rate was most rapid during the first two weeks, averaging 685,000 per week during this period, with one intravenous injection per week. Two patients averaged an increase of 860,000 per cubic millimeter, during the first three weeks, and one patient increased at the rate of 1,220,000 per cubic millimeter per week.

In a group of ten patients with an average initial red blood cell count of 1.42 millions per cubic millimeter (1.09 to 1.89) it required an average of 50 days (30 to 79) to reach an average of 4.29 million per cubic centimeter (4.07 to 4.60). The average increase in red blood cells per week was 0.429 million per cubic millimeter during this period. Here also the rate was most rapid during the first two weeks, averaging 573,300 per week with one intravenous injection every seven days.

In a group of twenty-one patients with an average initial red blood cell count of 2.63 million (2.01 to 3.0) it required less than an average of 42.9 days (18 to 77) to reach an average of 4.38 millions per cubic centimeter (4.01 to 5.49). The actual time is probably somewhat less than this, as the patients did not report at as frequent intervals as when the counts were lower, and

so intervals of from one to three weeks may have elapsed after the counts reached 4 million. For this reason it was not feasible to estimate exactly the rate of improvement of eleven additional patients whose initial red blood cell counts varied from 3.04 to 3.81 millions and whose post-treatment counts were from 4.0 to 5.14 million per cubic millimeter.

⁷ Hirschfeld, Samuel, Hyman, H. T. and Wanger, Julius J. Influence of Velocity on the Response to Intravenous Injection. Arch. Int. Med. 47: 219 (1931) 1931.
⁸ Riddle, M. C. and Sturgis, C. C. The Effect of Single Massive Doses of Liver Extract on the Blood in Patients with Pernicious Anemia. Am. J. M.

There is some evidence that when intravenous injections are given more frequently than once a week the response is more rapid up to a certain physiologic maximum

MAINTENANCE DOSE

In fifty-six patients observed for a period of from six to seventeen months after the red blood cell count reached 4 million per cubic millimeter or over, it was found possible to maintain the normal level with one injection a month. Individual patients remained normal with injections at intervals of eight and twelve weeks. Patients with infections, especially cystitis, as well as those with arteriosclerosis, require more frequent treatment than others. In the four week group the contents of 13 vials (3 Gm) of liver extract of the orally administered type supplanted the dosage of 84 vials given by mouth. Up to the present, four patients have been maintained on one injection a month for seventeen months, twenty-three patients for twelve months or

ties, and an ataxic gait. The history of the disease extended back at least four years, and the neurologic symptoms had been an outstanding feature for a year. He had lost control of his feet one month before entering the hospital. The blood count on admission was 3,040,000 red blood cells per cubic millimeter, the hemoglobin was 63 per cent (Sahl). The lowest red blood cell count was 2,450,000 per cubic millimeter. The knee jerks and achilles response were hyperactive. There was a bilateral positive Babinski reflex and a positive Romberg's sign. The sense of motion and position were lost in the great toes, and the vibratory sense was diminished over both tibias, markedly so over the ankles, being completely lost on the right side. A slight diminution of pain, touch and temperature sense was noted in the legs. Tenderness of the achilles tendon was preserved. The patient was treated with liver extract intravenously, first at intervals of two weeks but monthly after the fourth dose. The neurologic symptoms improved steadily, and he was able to return to his work as a barber within five months. At the end of ten months the sense of position and motion of the toes was perfectly normal, the positive Babinski sign had disappeared, and sensation was normal. The vibratory sense had returned, although still diminished below normal in intensity. This, with brisk knee jerks, was the only neurologic abnormality.

INDICATIONS FOR INTRAVENOUS LIVER EXTRACT THERAPY

While the intravenous route may be used as a routine in the treatment of the average patient, it is especially applicable to patients who are unable or unwilling to take the medication by mouth. A small group of patients fail to respond to oral medication and in these individuals the intravenous route is necessary. Because of the long intervals between the doses, and the lack of discomfort, many patients prefer the intravenous method to the intramuscular route. The intravenous method also

Chart 3—Reticulocyte and red blood cell changes in a patient who did not respond adequately to large doses of liver extract and desiccated hog stomach, but who showed a normal recovery with liver extract intravenously. The subsequent counts, following those plotted in the chart, are shown in the inset table. A, desiccated hog stomach started, B, desiccated hog stomach stopped.

longer, and twenty-five patients for ten months or longer without relapse (tables 2 and 3).

As previously mentioned, the actual maintenance dose for each individual must be determined separately, as some will no doubt require treatment at more frequent intervals.

The intravenous method of treatment fulfils ideally the postulates of Minot⁹ concerning adequate therapy. First, a large reserve supply is set up in the body so that sufficient material is available for all possible uses of the active substance. Secondly, as shown by the observation of fifty-six patients of this group from six to seventeen months, no neurologic progression has been noted, in fact, the same degree of improvement in the combined system disease as is noted with adequate liver therapy has invariably followed.

As an example of improvement in the neurologic features, the following report shows the adequacy of the intravenous method of treatment for this feature.

CASE 1—A white man, aged 49, a barber, entered the hospital because of nervousness, irritability, weakness, edema of the feet, ankles and hands, numbness and tingling of the extremi-

ties, and an ataxic gait. The history of the disease extended back at least four years, and the neurologic symptoms had been an outstanding feature for a year. He had lost control of his feet one month before entering the hospital. The blood count on admission was 3,040,000 red blood cells per cubic millimeter, the hemoglobin was 63 per cent (Sahl). The lowest red blood cell count was 2,450,000 per cubic millimeter. The knee jerks and achilles response were hyperactive. There was a bilateral positive Babinski reflex and a positive Romberg's sign. The sense of motion and position were lost in the great toes, and the vibratory sense was diminished over both tibias, markedly so over the ankles, being completely lost on the right side. A slight diminution of pain, touch and temperature sense was noted in the legs. Tenderness of the achilles tendon was preserved. The patient was treated with liver extract intravenously, first at intervals of two weeks but monthly after the fourth dose. The neurologic symptoms improved steadily, and he was able to return to his work as a barber within five months. At the end of ten months the sense of position and motion of the toes was perfectly normal, the positive Babinski sign had disappeared, and sensation was normal. The vibratory sense had returned, although still diminished below normal in intensity. This, with brisk knee jerks, was the only neurologic abnormality.

enables the physician to give a definite amount of medicine at known intervals, a feature which we have found to be an important cause of relapse when the patients are left to themselves to take the liver extract by mouth. The intravenous route makes it possible to give effective doses to patients who are nauseated or who vomit their food, and is, of course, the method of choice for comatose or irrational individuals.

A case illustrating the inability to use even large doses of potent material by mouth with quick relief by intravenous treatment is shown in the following report.

CASE 2—A man, aged 22, entered the hospital in his fifth relapse, his disease having dated back four years. He had had remissions induced by liver and by liver extract. In the previous relapse he had responded only to the juice of from 1 to 3 pounds of liver a day, desiccated hog stomach in doses up to 150 Gm daily for eighteen days having proved ineffectual. It required from 6 to 10 vials of Lilly's liver extract (343 N N R) to maintain his blood count at a normal level. When this was discontinued a relapse set in within a month. He was then given desiccated hog stomach, from 40 to 50 Gm a day, with a markedly submaximal response in both reticulocyte and red blood cell production (chart 3). He was then given liver extract intravenously and responded perfectly. Defective absorption of the active material from the gastro-

9 Minot G R The Importance of the Treatment of Pernicious Anemia on a Quantitative Basis J A M A 99 1906 (Dec 3) 1932

intestinal tract was the probable mechanism of the failure of medication by mouth, as nausea, vomiting and diarrhea were clinical features until the remission was induced

NATURE OF THE HEMATOPOIETICALLY "ACTIVE PRINCIPLE" OF LIVER EXTRACT

As the active substance is not held by permutite, it must be different in nature from histamine, tyramine, epinephrine, choline, hordenine, trimethylamine, lysine, histidine, piperidine, glucosamin, guanidine, hydroxylamin and lecithin. The other steps in the process of manufacture of the active extract eliminate the proteins. It is nonlipoid, as material extracted with ether or acetone is potent. Of the substances which are not held back by permutite, it is known from clinical tests that glutamic acid, cystine or cysteine is not effective

SUMMARY AND CONCLUSIONS

1 Substances causing reactions when liver extract is given intravenously may be removed by treatment with permutite and acetone

2 Intravenous injections of the extract made from 100 to 125 Gm of liver may be given weekly to patients with pernicious anemia until the red blood cell count is normal, then once every month as a maintenance dose. Proper checks should be used to determine the dosage required for each individual patient

3 A characteristic "reticulocyte response" is induced by this type of therapy, but the average maximum percentage is higher than that reached after about forty times as much material as is usually taken by mouth in divided doses daily

4 The subjective changes and neurologic improvement are marked features with this type of therapy

5 The intravenous method presents a distinct economy in the use of liver material and allows the patient freedom from daily medication, and a non-limited diet. It also assures the physician that the patient is taking a known dose of potent material at regular intervals

6 A favorable response is obtained by the intravenous use of liver extract in a small group of patients with pernicious anemia who do not respond to liver or desiccated hog stomach when given orally

Task of Purging the Materia Medica—Research in therapeutics can for convenience be considered from three angles—experimental pharmacology, chemotherapy, and experimental therapeutics—and in the case of new drugs investigation generally follows this logical sequence. This has not been, however, in the case of a large proportion of the drugs which are still in use, the historical order. It has been computed that about 50 per cent of the drugs in our present Pharmacopoeia were in use by the Arabic speaking physicians of the Middle Ages. Many others like cinchona and ipecacuanha, came to us early from the New World. All these had been first tested by direct observation of their effects on disease in man. Modern medicine acquired an unwieldy heritage of drugs so introduced. When the new science of experimental pharmacology began roughly about a century ago it was confronted with the Augean task of purging the materia medica of an accumulation of inactive and useless drugs. Experimental pharmacology at first led not to an increase, but to a decrease in the number of remedies in use. What frequently happened was that a reputed remedy when examined pharmacologically, failed to display such actions as could explain its therapeutic use. This led to a re-investigation of its therapeutic claims which were often proved to be ill founded and it was eventually discarded. It must be admitted however, that in this process of elimination pharmacology made many mistakes—Gibbs and A. Remarks on the Outlook of Research in Therapeutics *Bull. N. Y. Acad. Med.* 2: 89 (Aug. 27) 1932

THE EFFECT OF THEELIN INJECTIONS ON THE CASTRATED WOMAN

AUGUST A. WERNER, M.D.

WITH HISTOLOGIC REPORT BY

W. D. COLLIER, PH.D., M.D.

ST. LOUIS

The object of these experiments was to determine the effect of various dosages of theelin on human female castrates of different ages and varying length periods of castration. It was of particular interest to study the effect of this hormone on the subjective symptoms that accompany castration and on the involutionary changes that occur in the breasts and the genital tract following ovariectomy.

Stockard and Papanicolaou¹ described an exact method for following the estrual changes in the living guinea-pig by the vaginal smear. This method has been applied to the correlation of the estrual phenomena in the genital organs of the rat² and the mouse³. Allen and Doisy,⁴ employing ovarian follicle fluid from hogs, produced pubertas praecox in immature albino rats. The vagina of the immature rat is completely closed, its external third being a solid cord of cells. They found that the injection of the ovarian follicular hormone into immature rats, both normal and spayed, induced a sexually mature condition in the genital tract similar to that of an animal experiencing its first estrus. This was effected in from two to three days by from four to six injections of an active extract at an age as early as 26 days, or from twenty to fifty days before the usual time of the attainment of puberty. This work was later confirmed by Frank, Kingery and Gustafson.⁵

Allen and Doisy⁶ also devised a simple method of testing the potency of the follicular hormone by injecting a potent extract into spayed rats in which there was atrophy of the vaginal epithelium with the production of the estrous cycle on the third day.

Frank⁷ has demonstrated that an analogous potent hormone can be obtained from the follicles, the corpus luteum, the placenta and the blood of pregnant women. Allen, Pratt and Doisy⁸ determined quantitatively the ovarian follicular hormone in the follicle, corpus luteum and placenta of the human female and of some animals, including the cow and the pig.

Zondek and Aschheim, in 1927, found that the urine of pregnant women contains large quantities of the follicular hormone. Doisy,⁹ using such urine, was able to isolate the follicular hormone in crystalline form. This substance, like other isolated hormones, is of great potency.

From the Departments of Internal Medicine and of Pathology, St. Louis University School of Medicine.

Because of lack of space this article is abbreviated in THE JOURNAL by the omission of a chart and the day by day reports of the cases. The complete article appears in the authors' reprints.

CONCEPT OF OVARIO-UTERINE (MENSTRUAL) CYCLE

A great amount of experimental work has been done in the past few years to determine the relationship of the anterior lobe pituitary sex hormones and the ovarian follicular and luteal hormones to menstruation. The human female, female apes and old world monkeys are the only animals that menstruate in the ordinary sense of the term.

Hitschman and Adler first described the well known so-called premenstrual changes that occur or were supposed to occur before each menstruation. Their theory did not associate the anterior lobe pituitary with the ovario-uterine cycle. The sequence of events in the human reproductive cycle according to this theory was that ovulation is a periodic function occurring regularly about the middle of the interval between two menstrual hemorrhages. The ruptured follicle from which the ovum has been extruded then develops into the corpus luteum, and this newly formed structure, acting as a gland of internal secretion, causes the development of the pregravid changes in the endometrium which are necessary for implantation of the fertilized ovum. If, however, the ovum is not fertilized, the corpus luteum regresses, and degeneration of the pregravid endometrium takes place with consequent menstruation. According to this idea, menstruation may be defined as bleeding from the uterus as a result of regressive changes occurring in a pregravid endometrium following the failure of implantation of a fertilized ovum.

ANTERIOR LOBE PITUITARY SEX STIMULATING HORMONES

The experimental demonstrations by Smith and by Smith and Engle¹⁰ of a follicle-stimulating hormone of the anterior lobe pituitary, and by Evans and Long¹¹ of a luteinizing hormone¹² from the same gland, have made the utero-ovarian cycle seem a bit more complicated.

Without the anterior lobe follicle-stimulating hormone, graafian follicle development and ovulation will not take place, and presumably, without the anterior lobe luteinizing hormone, the corpus luteum will not be formed at the site of the ruptured follicle. To carry this process one step further, without a corpus luteum no premenstrual changes will take place in the endometrium, and according to the older theories no menstruation will occur.

Sufficient experimental work has been done at the present time to question seriously, if not disprove, the idea that menstruation must occur from a pregravid endometrium.

Heape,¹³ working in India, collected many menstruating uteri of *Semnopithecus* and *Macacus rhesus*, very few of which were accompanied by ovaries containing corpora lutea.

Van Herwerden¹⁴ made a careful study of the uteri of eighty-seven of the Java macaque in which she found two types of uteri. 1 Those with a narrow mucosa, resting glands and poorly developed arterioles, in none

of these cases was there a corpus luteum. 2 Uteri with swollen mucosa, secreting glands, and thick-walled arterioles, all associated with corpora lutea. On the basis of these studies she postulated a breeding season in which the sexual cycle is characterized by ovulation, corpus luteum formation and the pregravid endometrium, with the possibility of conception. Alternating with this is the nonbreeding season, in which menstruation continues without ovulation and corpus luteum formation.

This work has been confirmed by Hartman,¹⁵ Corner,¹⁶ Edgar Allen¹⁷ and others, and by a long series of observations in the monkey colony of the Carnegie Institution at Washington, D. C.

Corner¹⁸ explored histologically the genital tract in a number of individuals of *Pithecius rhesus*, in which an accurately recorded, fairly regular menstrual cycle had been obtained. Only five animals were killed during menstruation, two on the first day of menstruation and three on the fourth. The endometria were dissimilar, only one showing the expected premenstrual growth. His work established beyond doubt the occurrence of menstruation in monkeys possessing a low, extremely simple and intact endometrium, the ovaries being without signs of preceding ovulation. He says

Histologically there are two types of menstruating endometrium, one showing premenstrual changes, the other devoid of them according to the occurrence or nonoccurrence of ovulation twelve to fourteen days beforehand. That the hemorrhage is one and the same phenomenon under these two different circumstances is of course my own assumption, but at least, the burden of proof now seems to be on the other side.

This work seriously questioned the correctness of the Hitschman-Adler theory of menstruation, founded on the gradual upbuilding and sudden destruction of the endometrium, which is generally thought to be the cause of menstruation.

Edgar Allen¹⁹ was able to produce menstruation in eight ovariectomized monkeys by the injection of follicular and placental extracts. Menstruation began within a few days after cessation of the hormonal injections. In these experiments, full premenstrual development of the endometrium was not obtained. He says "Theelin, alone of ovarian hormones, seems sufficient to supply the essential mechanism of menstruation." Allen²⁰ further states

Theelin produces the growth phase in the accessory genital organs. This includes accelerated growth of the vaginal epithelium, growth of the glands of the cervix and body of the uterus to the interval condition, probably some repair of ciliation of the tubes, and, toward the end of this interval, the initiation of growth in the mammary gland tree including the nipple.

EXPERIMENTATION ON WOMAN

The facts that previous experimental work on monkeys showed that menstruation may take place regularly without pregravid changes in the endometrium, and that a series of injections of follicular extracts into ovariectomized monkeys was followed by the onset of menstruation, stimulated the desire to determine, if possible,

12 There is much question at the present time as to the existence of a separate luteinizing hormone. The generally accepted idea is that there is one anterior lobe sex stimulating hormone which produces sexual development and the premenstrual ovarian phenomena.

the effect of theelin on the uterus of the ovariectomized woman. A search of the literature does not reveal that this work has been done by a previous investigator.

The two outstanding difficulties encountered in attempting this work were, first, to obtain suitable subjects, and, second, to maintain unflinching cooperation. From a perusal of clinic and private records accumulated over a period of ten years, a list of about sixty castrated women was compiled. Out of this number eight women were found who were suitable for the work, and of these eight women only five gave their consent to assist in the experiments. These patients were told beforehand just what the method of procedure would be, that they would have to be seen daily, that they were to receive large doses of theelin over long periods of time and that they would have to submit to light curettages from time to time as was deemed necessary. The cooperation by these patients was perfect, not one injection was missed and all necessary curettages were assented to willingly.

The patients were observed daily, the breasts and genitalia were frequently examined, especially if any statement of a patient suggested some change of possible importance. Any changes in subjective symptoms were noted. These symptoms were described in a previous article²¹ based on a study of forty castrates and ninety-six cases of menopause.

THE PATIENTS USED

Four women who had complete bilateral ovariectomy performed and whose uteri were intact and one woman (patient 2) whose uterus had been removed were used in these experiments.²² Amenorrhea was complete in all since operation, except in patient 3, aged 28, who had been operated on four years previously. She menstruated regularly but scantily for one or two days for five or six months following the operation, but during the last three and a half years she had been completely amenorrheic. All patients had atrophy of the breasts and had had no noticeable vaginal mucous discharge since operation. All complained bitterly of the symptoms that accompany ovarian hypofunction, and this symptom was the chief factor which made it possible for them to submit to the experiment.

The physical examination of each patient did not reveal any abnormality except those mentioned. The pulse rate and blood pressure were normal in each individual.

LABORATORY EXAMINATIONS

All the patients had a hemoglobin determination, a red and white count, blood picture, Kahn test, urinalysis, basal metabolism test, five hour sugar tolerance test, electrocardiogram and photographs in the nude to show the type of the individual. All tests were normal in each patient.

EXPERIMENTAL PROCEDURE

Since it was desirable to know what effect theelin would have on the uterus and endometrium, it was necessary to do a preliminary curettage before beginning treatment. The cervix in each case was pale pink, and the cervical canal was contracted. For the first curettage each patient needed a forceful dilation, and patient 4 submitted to a general anesthetic, which was necessary for the first dilation.

INJECTIONS OF HORMONE

Theelin was the hormone used in all experiments.²³ In the literature relating to the experimental work done on animals, the authors frequently expressed doubt that sufficient theelin could be given to women to produce the results obtained in small animals. As there was no available information as to how much theelin might be necessary to accomplish this result, and as it was not known what untoward clinical or tissue reaction might be encountered, it was necessary to proceed carefully.

Following the initial curettage, each patient was given 4 cc of theelin, equivalent to 200 rat units daily, for twenty-eight days, 6 cc or 300 rat units daily the

TABLE 1—Observations in Five Castrated Women Before Treatment with Theelin

second twenty-eight day period, and 8 cc, or 400 rat units, daily the third twenty-eight day period. These injections were made about 1 inch deep into the upper gluteal region about 3 inches below the iliac crest, on alternate sides daily. A slight local burning sensation was noticed for about five minutes at the site of injections only after doses of from 6 to 8 cc were reached. During the last half of the 8 cc dosage period, injection areas were sensitive to pressure. These areas were exceptionally free from induration except in patient 2, who had a low-grade sterile abscess without rise of temperature in the left area at about the middle of the third twenty-eight day period. Patient 4 never experienced discomfort at any time. On the first, seventh, fourteenth and twenty-first days of the first twenty-eight day period, each patient was lightly curetted so that endometrial tissue might be obtained to determine what histologic changes, if any, had occurred. No anesthetic was used. After the fourth curettage it was decided that these operations were too frequent and if menstruation did take place, the objection would be raised that the women were bleeding from the curettages and not as a result of the hormone injections. Therefore, no more curettages were to be done unless some of the patients menstruated.

On the forty-fourth day, patient 1 had been bleeding from the uterus and vagina for eighteen hours, and

²³ A plentiful amount of this hormone was supplied by Parke Davis & Co.

²¹ Werner, A. V. Symptoms Accompanying Ovarian Hypofunction. *J. Missouri M. A.* 36:3369 (Aug.) 1931.

²² Correction: Patient 2, aged 40, who was used in the experiments evidently had the uterus removed. This woman had had the laparotomy done by a physician in his private office and was immediately removed to her home. No record was obtainable and no statement could be had from the physician. The patient was not certain as to what organs had been removed. One of the gynecologists who assisted me made an examination of the patient and decided that the uterus had not been removed. Although the supposed uterus was small and the depth of the cavity including the cervical canal by measurement was 1½ inches, or 1.5 inch, this was thought to be due to atrophy as a result of the operation. This woman was treated as the other patients were for the first eight days and then for two and one-half months subsequently but she gave no evidence of menstruation. Tissue obtained from seven curettages at various times throughout the experiment failed to show any endometrial tissue at any time in other words only cervical tissue was obtained. The lack of tissue lead to the conclusion that patient 2 had the uterus removed and had a long cervical canal. It would seem she had a "cervix" in every way as did the other patients except that her "cervix" was impossible for her record will be retained in the file.

at that time she was curetted. Except for this instance, no more curettements were done until at the end of the third twenty-eight day period, when all patients were curetted. At that time injections were to be discontinued to see whether menstruation would occur, as had been the experience of Allen in previous experiments on monkeys. To obviate the objection that bleeding was due to the last curettement, if these women menstruated following cessation of injections, the injection of 8 cc daily was continued for one week past the last curettement.

REPORT OF CASES

CASE 1—A white woman, aged 31, married, the mother of three children, 64¼ inches (163 cm) tall and weighing 159 pounds (72 Kg) nude, had had a bilateral salpingo-ovariectomy six and a half months previous to the onset of the experiments. Amenorrhea was complete and there had been no mucous discharge from the vagina since the operation. The breasts were relaxed and flabby. She had nine symptoms that accompany ovarian hypofunction.

CASE 2—A white woman, aged 40, married, the mother of one child, 59¾ inches (152 cm) tall and weighing 147 pounds (66.7 Kg) nude, had had a bilateral salpingo-ovariectomy and supracervical hysterectomy seventeen months previous to the beginning of the experiments. She had had amenorrhea since the operation. There had been no discharge of mucus from the vagina since operation. She had sixteen symptoms that accompany ovarian hypofunction.

CASE 3—A white woman, aged 28, 63½ inches (161 cm) tall and weighing 112 pounds (50.8 Kg), divorced, had had one abortion ten years before. A bilateral salpingo-ovariectomy had been done four years before. The patient menstruated from one to two days scantily each month for five or six months following operation. Amenorrhea was complete for the past three and a half years. She had nineteen symptoms that accompany ovarian hypofunction.

CASE 4—A white woman, aged 30, married, 64½ inches (164 cm) tall and weighing 174 pounds (79 Kg) nude, had had one full term pregnancy at the age of 17. A bilateral salpingo-ovariectomy had been done five years and nine months before. Since then, the patient had had amenorrhea, she had fourteen symptoms that accompany ovarian hypofunction.

CASE 5—A white woman, aged 22, divorced, 64½ inches (164 cm) tall and weighing 128 pounds (58 Kg) nude, had never been pregnant. Fifteen months before, she had a bilateral salpingo-ovariectomy. She had amenorrhea since the operation, with marked decrease in libido. She had fourteen symptoms that accompany ovarian hypofunction. The vaginal orifice admitted two fingers, the cervix was of normal size, firm and pale pink, there was no mucous discharge from the external os.

COMMENT

Human ovariectomy is followed in a rather short period of time by several characteristic phenomena, among which may be mentioned atrophy of the genitals, probably most noticeable in the uterus, amenorrhea, atrophy of the breasts, and a train of subjective symptoms due to autonomic nervous system imbalance. Scientific medical literature is replete with the results of experimentation on castrate laboratory animals, including the monkey, in which the various preparations of follicular hormone and theelin were used. These animal experiments give ample proof that the follicular hormone stimulates growth and certain functions of the accessory genital organs. The interesting work done on monkeys by Edgar Allen, Corner, Hartman, Robertson,²⁴ Morrell,²⁵ and other investigators approaches experiments on the human being.

The question has always remained as to whether women would or would not respond to injections of follicular hormone as did the monkey.

EFFECT OF THEELIN ON THE BREASTS

The first question to be asked is Will theelin restore the breasts and genital tract to normal development after castrate atrophy? All the patients experienced activity in the breasts, characterized by a sensation of fullness and actual enlargement, tingling in the gland tree and erection of the nipples. This was first noticed by patient 1 ten days after the onset of treatment, it was noticed in patient 2 on the ninth day, in patients 3 and 5 on the seventh day, and in patient 4 on the fourth day. These breast changes were constant throughout the treatment after their first appearance. In patient 2, a cloudy fluid not unlike colostrum could be expressed at all times following the onset of breast changes.

EFFECT OF THEELIN ON THE UTERUS

All patients had atrophy of the cervix and uterus (except patient 2, who had no uterus) as evidenced by the size and pale pink color of the cervix and the necessity of forceful dilation in all, which procedure required a general anesthetic in patient 4. Also, there was absence of noticeable mucous flow since castration, except in patient 3, and she had had no mucous discharge for the past three and a half years. Microscopic examination of specimens obtained at the first curettage before the onset of treatment revealed a markedly atrophic endometrium in patients 1, 3, 4 and 5.

On the seventh day after the onset of treatment, the cervix was darker and more vascular, and the canal was easily entered in patients 1, 3, 4 and 5. In patient 2 this was noticed the second week. Mucous discharge in such amount as to soil the underwear was first noticed in patient 1 on the fourteenth day, in patient 2 on the ninth day, in patient 3 on the seventh day, in patient 4 on the fourth day, and in patient 5 on the third day. These signs of activity in the cervix and uterus were continuous and increasingly prominent throughout the treatment.

Uterine bleeding occurred in all patients except patient 2. This patient showed increased vascularity of the cervix with mucous discharge and breast changes.

Patients 1, 3, 4 and 5 had uterine bleeding while receiving injections, and patients 3, 4 and 5 also bled after cessation of treatment. The bleeding in all patients, whether receiving injections or after their cessation, was always accompanied by the symptoms that usually accompany menstruation in most women. These women say that they feel as if they would menstruate or that they are fatigued and have a generalized aching, so frequently spoken of as a "no-account" feeling, they are tired and rather peevish. Accompanying this is low lumbosacral backache and a sensation of abdominal fullness and bloating, the pelvic organs feel heavy, and there are intermittent cramps of varying severity with a bearing-down sensation, which has been described as a feeling of the pelvic organs pushing out. The breasts are full, tense and tender, and the nipples are erected. The patients and the napkins had the characteristic odor that accompanies menstruation.

Patient 1 had uterine bleeding four times while on the treatment. The first hemorrhagic flow began on the tenth day following the onset of injections and three days following a curettage. The flow of blood was free and she saturated two napkins each day. The

²⁵ Morrell, J. A., Powers, H. H., Verley, J. R. and DeFrates, J. The Results of Oral Administration of Amniotin to Monkeys, *Endocrinology* 14: 174 (May-June) 1930.

second period of bleeding began on the forty-fourth day, twenty-two days following a curettement, and lasted four days. The third bleeding began on the sixty-fourth day, twenty days following a curettagement, and lasted twenty-four hours. The fourth bleeding began on the eighty-fourth day, which was the end of the third twenty-eight day period. Curettagement was done after the onset of bleeding. Microscopic examination of the endometrium obtained at the last two curettages, which were done in the presence of bleeding, showed that these two specimens approximated the histologic changes characteristic of the interval endometrium of the normal ovario-uterine cycle.

The first endometrial specimen from patient 1 showed an old endocervicitis. That the bleeding in this case was not a result of the endocervicitis is evidenced by the fact that the patient had not bled before treatment, and all hemorrhages were accompanied by the usual characteristic signs and symptoms that accompany menstruation, both uterine and subjective. The two last specimens of endometrium obtained showed that the endometritis had cleared, and in these instances the bleeding could not be attributed to infection or inflammation.

Patient 3 had uterine bleeding three times while on treatment and once following cessation of injections. Each bleeding period was accompanied by the usual symptoms that accompany menstruation. The first bleeding began on the fifth day after the onset of treatment and lasted two days. The second bleeding began on the eleventh day and lasted twenty-four hours, and the third flow of blood began on the thirty-ninth day, eleven days after a curettagement, and continued for two days. The fourth bleeding began ten days after the end of the third twenty-eight day period, ten days after the last curettagement and three days following the cessation of injections, and lasted four days. The endometrium in patient 3 closely approximated the interval stage of development.

Patient 4 was beginning to bleed on the eighty-fourth day of treatment, which was the end of the third twenty-eight day period. A specimen of endometrium obtained on this day showed by histologic examination that it had reached the full interval stage of development. Five days after cessation of injections and two days following curettement, the patient bled for two days. Both of these bleeding periods were accompanied by the usual signs and symptoms that accompany menstruation.

Patient 5 had uterine bleeding twice while receiving the injections and once after cessation of treatment. The first bleeding occurred sixteen days after the onset of treatment. The second bleeding began on the fifty-ninth day, thirty-eight days after the last curettagement. The third bleeding occurred ten days following the last curettagement at the end of the eighty-fourth day and three days after cessation of injections. She bled four days total. All three of these bleedings were accompanied by the usual signs and subjective symptoms that accompany menstruation and the endometrium closely approximated the interval stage of development.

REVIEW OF SUBJECTIVE SYMPTOMS

All these patients had most of the subjective symptoms that accompany castration or ovarian hypofunction. Patient 1 was free of these symptoms about the twentieth day, patient 2 had marked improvement after the ninth day, but she later developed a sinus infection,

which caused some trouble. Patient 3 had improvement by the sixth day and felt normal within two weeks. Patient 4 was symptom free after the sixth day, and patient 5 after the seventh day.

EFFECT OF THEELIN ON LIBIDO

Patient 1 stated that she had increased libido after the third injection, patient 2 at five weeks, patient 3 at 7 weeks, patient 4 after the seventh day. As treatment progressed, this impulse became more compelling. Patient 5, aged 22, stated that "sexual desire was markedly decreased following the ovariectomy and that the injections of theelin had not increased it."

IRRITATION FROM INJECTIONS OF THEELIN

One would think that the continuous injection of such large amounts of any substance would cause excessive irritation.

TABLE 2—Observations in Five Castrated Women After Treatment with Theelin *

	Patient 1	Patient 2	Patient 3	Patient 4	Patient 5
Total days of continuous injections	93 days	89 days	91 days	91 days	91 days

Endometrial hyperplasia	Yes	No	Yes	Yes	Yes
Irritation from injections	After 8 cc dosage	After 6th week dosage	After 6 cc dosage	None	After 8 cc dosage

* All patients received 200 rat units of theelin during the first twenty-eight days, 300 rat units during the second twenty-eight day period and 400 rat units during the third twenty-eight day period.

† Bleeding, before curettements.

Patients 1 and 5 did not have any irritation until the dosage reached 8 cc. They then noticed a burning for about five minutes after each injection, which would pass away. Patient 2 had a severe induration in the left area at about the sixth week, unaccompanied by rise of temperature, which required seven weeks before it disappeared. At about the eighty-fourth day an induration developed in the right area, which cleared up promptly. After the onset of the 8 cc dosage there was tenderness in the injected area if pressure was made. Patient 4 never experienced any discomfort.

HISTOLOGIC REPORT (BY DR COLLIER)

The description of the various bits of endometrium obtained by curettagement are based on paraffin sections of the scrapings. The descriptions are confined to the largest bits of material that appear to be sectioned in a plane at right angles to the plane of the endometrial surface.

The first patient had a complicating factor of endometritis and endocervicitis, which made it difficult during the early part of the experiment to separate the changes produced by infection from those produced by theelin. The material obtained before the beginning of the experiment showed the least degree of atrophy that was found in any of the patients before the beginning of theelin administration. This might be expected, since the patient had been castrated only about six months prior to this curettage. There was a moderately thinned endometrium with a few shallow glands and an edematous, leukocytic infiltrated stroma. The inflammatory edema and leukocytic infiltration made the tissue appear less atrophic than it actually was. The bits of cervix obtained showed a chronic inflammatory reaction with superficial erosion and a metaplasia of columnar epithelial cells to the stratified squamous variety not only on the surface but also extending into the necks of many of the cervical glands. The deeper tissues were infiltrated by a moderate number of leukocytes, mostly lymphocytes and plasma cells, and more or less recently formed fibrous tissue.

Examination of the endometrial scrapings obtained a week after the beginning of theelin administration showed an increased activity of the inflammatory reaction already present at the beginning of the experiment.

Fig. 1—Atrophic endometrium caused by castration. Condition before injections of theelin. A, patient 1, B, patient 3, C, patient 4.

No such inflammatory reaction was found to arise in any of the other patients of this series after the beginning of the experiments, so that one can be sure that the inflammatory reaction in this patient was in no way related to the theelin administration. It is probable that the mechanical irritation of the initial curettage stimulated the already existing process. It will also be seen that this inflammation cleared up during the course of the experiment while theelin was being administered.

A section of the endometrial scrapings taken two weeks after the beginning of the experiment still showed marked inflammatory reaction, so that any changes due to theelin were obscured if present.

A section of the scrapings obtained one week later showed a diminution of the inflammatory reaction. It was difficult to state the exact degree of true hyperplasia, although some degree was evident. The endometrium had not only become increased in thickness but had also become more completely differentiated into a more normal appearing tissue. This statement will be amplified in the description of the theelin induced changes in the other patients, since some might wish to believe that the changes in this patient were not due to theelin but were due to inflammatory repair.

A section obtained from scrapings removed twelve weeks after the beginning of the experiment showed a complete disappearance of the previous inflammatory reaction. There was a moderate increase in thickness

of the endometrium over that obtained at the beginning of the experiment, although it was still less in amount than is found in scrapings of normal uterus during the interval stage. The glands were more numerous and more complicated than those found in sections taken at the beginning of the experiment. The stroma density and cell type was quite normal in appearance but contained an unusual number of markedly congested vessels. This congestion was not related to the previous inflammatory reaction, because it became marked only during the period in which the inflammation was clearing, and it will be found later that this congestion is a prominent finding after theelin administration and is obviously a theelin effect.

The second patient of the series yielded scrapings that showed only strands of epithelium of the cervical type. At no time was it possible to demonstrate endometrial tissue from the fundus. It was found later that this patient had part (or all) of her uterus removed. From the evidence gained from six curettements on this patient, it is certain that the endometrium of the fundus had been completely removed. The only change in the cells during the experiment was a greater secretory function after theelin administration.

The third patient had a markedly atrophic endometrium at the beginning of the experiment. A section of the scrapings showed only strands of epithelium with a few adherent stroma cells. There was no evidence of gland formation. I doubt that there was a complete absence of glands, but there must have been a few glands, since none were seen in all the material, and they must have been exceedingly shallow, the scrapings were so thin.

There was no change from this pretheelin appearance of the endometrium in sections taken from material removed one, two and three weeks after the beginning of theelin administration.

A section of endometrial scrapings removed twelve weeks after the beginning of theelin administration and nine weeks after the last material mentioned showed a considerable endometrial growth. There was not only an increase in thickness of the endometrium but also a better differentiation of the tissue. The epithelial cells were better formed, more hyperchromatic and more numerous per unit of surface space. The glands were few but relatively deep. They showed some branching and some dilatation of the lumens but showed no intraluminal papillary projections. The stroma cells were of normal form in contrast to the edematous, mucoid state found previously. The stroma was quite compact for the most part but congested with blood in numerous large, endothelial lined blood spaces in the stroma.

A section of the endometrial scrapings of the fourth patient taken before the beginning of theelin administration showed a slightly less degree of atrophy than in patient 3, although patient 4 had been castrated almost two years longer than patient 3. There was only an occasional shallow gland and only a slightly greater amount of stroma. The stroma was of the same loose, pale staining character that has been found previously before theelin administration.

Sections of scrapings taken one and two weeks after theelin administration showed no appreciable change.

A section from scrapings taken a week later showed a considerable increase in the amount of endometrium. The thickness was greater than that found in patients 1 and 3 after twelve weeks of theelin administration, and the experimental period about four times as long as the duration of the experiment in this case. A few rather

deep glands were found. The stroma is largely of the compact normal type but there are a few patches of edema and a number of large vascular spaces.

A section of the scrapings removed nine weeks later, after twelve weeks of theelin administration, showed a still greater increase in thickness of the endometrium. The thickness was as great as that of normal, interval endometrium, but the architecture of the endometrium differed greatly from that of normal endometrium in that there were peculiarities in the glands and a considerable subepithelial hemorrhage. It is to be remembered that this patient was bleeding from the vagina at the time this curettage was done. The glands were relatively increased in number in comparison with the previous sections from this patient but were absolutely less in number than would be found in a normal endometrium. These glands had lumens of various diameters. They were sometimes found to branch. Some were cystic with intracystic papillary projections. The uterine bleeding, the subepithelial hemorrhage, the compactness of the stroma, the irregularity of the glands and the intracystic papillary growths made a combination highly suggestive of Cullen's hyperplasia of the endometrium.

The last patient of this series presented no formed tissue in the sections made from scrapings taken before the beginning of theelin administration.

A week later, a few shreds of epithelium with a few adherent stroma cells were obtained on curettage.

After two weeks of theelin administration there was considerable hyperplasia of the endometrium, moderate congestion and only slightly increased density of the stroma, but a rounder and more normal type of stroma cell and a few shallow but normal appearing glands.

After the third week of theelin administration, the hyperplasia was still greater than that found in the preceding section, the glands were more numerous and showed a greater variation in size of the lumens and in tortuosity. The stroma was much denser, with the exception of large vascular spaces.

After twelve weeks of theelin administration, the endometrium was as thick as would be found in the normal interval stage, the stroma was normal in appearance but the glandular growth was both excessive and atypical, and congestion was marked. The glands were

Fig. 2—Hyperplasia of endometrium after theelin had been administered for eighty-four days: A, patient 3; B, patient 4; C, patient 5.

atypical in the same manner as was described at length in the last stage of hyperplasia in the previous case.

SUMMARY

The endometrium was found to be atrophic in the female castrate. The degree of atrophy was not found to be exactly proportional to the duration of castration. The atrophy was made evident by a decrease not only in the thickness of the endometrium but also in the number and in the depth of the glands and there was a change in the stroma to a looser more fibrillar and more spindle cell type.

After theelin administration, there was a hyperplasia of the endometrium. This became apparent as early as three weeks after the beginning of the experiment in three of the four cases in which endometrium could be demonstrated. There was not only an increase in the amount of endometrial tissue but also a redifferentiation of the stroma to its normal type and a better differentiation of the epithelium. The epithelial cells became more hyperchromatic and the cells developed a clearer cut appearance. The glandular growth was atypical in that the hyperplastic glands

Fig. 3—Condition of endometrium in A, patient 4, before administration of theelin; B, patient 3, after twenty-one days; C, after eighty-four days.

were irregular in form, similar to the appearance of glands in Cullen's hyperplasia of the endometrium. There is a markedly increased congestion of the tissue with the formation of large, thin walled vessels filled with blood.

There is no suggestion of premenstrual change of pseudodecidual formation from stroma cells in any of the material even though some of the sections were taken at a time when there was bleeding from the uterus. The endometrium presented a picture quite different from that of premenstrual swelling in many respects. The thickening of the endometrium was never found to exceed that of the normal resting or interval stage and therefore was never as thick as is found in the premenstrual swelling stage. The glands of theelin hyperplasia were quite irregular in the diameter of their lumens and showed intraluminal invaginations, neither of which are changes characteristic of premenstrual swelling but are typical of Cullen's hyperplasia of the endometrium. The stroma became more compact and the nuclei of the cells became more hyperchromatic, both of which are changes diametrically opposed to the changes of premenstrual swelling but are in full accord with the changes in Cullen's hyperplasia. There was no apparent loss of endometrial substance at the time of bleeding, such as occurs in menstruation, although the nature of the material makes it quite possible that there might be some loss of tissue which might be undetected. It is certain that there was quantitatively less loss of tissue in theelin induced bleeding than in normal menstruation.

CONCLUSIONS

1 Theelin restores the breasts and genital tract of women to apparently the normal sexual state after previous castration atrophy.

2 Theelin produces changes in the atrophied endometrium of castrated women that approximate or equal the interval changes found in the normal women at the time of ovulation.

3 Theelin does not produce the pregravid changes in the endometrium of castrated women

4 The bleeding from the uterus of castrated women induced by theelin occurs from an endometrium approximating or equaling in development the interval changes found in the uterus of normal women

5 Theelin induces bleeding from the uterus of castrated women qualitatively indistinguishable from menstruation in normal women

6 This bleeding from the uterus of castrated women is accompanied by the subjective symptomatology usually experienced by normal women during menstruation

7 Theelin relieves the subjective symptoms that occur in women following castration

8 Four ovariectomized women to whom large doses of theelin were given state that "libido was markedly increased"

9 Excessive doses of theelin were given to women intramuscularly over a period of from eighty-nine to ninety-three days without seeming discomfort, until a dosage of from 6 to 8 cc daily was reached

Grand Boulevard and Lucas Avenue

COARCTATION OF THE AORTA

TEN YEARS' OBSERVATION OF A PATIENT STILL LIVING

M J SHAPIRO, MD
MINNEAPOLIS

Coarctation of the aorta is a term used to designate a narrowing or complete obliteration of the aorta usually in the region of the insertion of the ligamentum arteriosum, the vestigial ductus botalli, distal to the origin of the subclavian artery. Bonnet has described two types of this condition: infantile and adult. Characteristic of the infantile type is a diffuse narrowing of the aorta between the origin of the subclavian artery and the insertion of the ductus botalli. Further, this type represents a persistence of the intra-uterine circulation, is accompanied by a patency of the ductus arteriosus and is incompatible with life. The adult form of coarctation of the aorta consists of a sharp narrowing even to the extent of complete obliteration in the immediate vicinity of the insertion of the ductus botalli. Abbott and Hamilton,¹ who have made the most complete study of this pathologic picture, describe adult coarctation as follows:

In the pronounced cases of this type the constriction is so sudden and deep that the descending arch appears as though a ligature had been tied tightly around it at the strangulated part, and above and below this the aorta bulges outward in hour-glass fashion. In other cases there is a gradual diminution of the aortic trunk from the innominate or the left subclavian, rapidly narrowing after the origin of the latter vessel to the point of constriction. Internally, the effect of the external strangulation in narrowing the lumen of the vessel is frequently accentuated by a fold or septum or diaphragm which stretches across what remains of the aortic lumen, either closing this or leaving a small central or lateral aperture, often triangular in shape which may admit a "bristle," "probe" or "cow-quill" according to the degree and nature of the stenosis. The great vessels of the arch, especially the innominate and subclavian arteries, with their branches, are usually more dilated as are the first three intercostals emerging below the

stricture and the deep epigastric artery, for it is by means of these vessels that the collateral circulation, by which life is maintained in the extreme cases, is chiefly carried on.

No review of the literature on this subject will be attempted here. This has been excellently and recently done by Dr. Abbott.

It is interesting to note the increase in the number of cases of coarctation of the aorta reported in recent literature. This seems to indicate that this condition is not as rare as formerly supposed. Apparently the condition was not well understood and the diagnosis therefore missed. The diagnosis is not difficult to make when one keeps this cardiac anomaly in mind. As happened in the case here reported, coarctation is often mistaken for juvenile hypertension. The diagnosis is made on four characteristic observations: (1) hypertension of the upper extremities, (2) lowered or absent blood pressure of the lower extremities, (3) evidence of collateral circulation, and (4) erosion of the under surfaces of the ribs as demonstrated by roentgen examination. The erosion is caused by the dilated and tortuous intercostal arteries, which carry the brunt of the collateral circulation made necessary by the narrowing or complete obliteration of the aorta.

REPORT OF CASE

A boy first visited Lymanhurst Heart Clinic in 1923, when he was 7½ years old. There was nothing unusual in his past history. His mother stated that the family physician had diagnosed a "weak heart" at the age of 3 weeks. The boy looked unusually well, he was well nourished and especially well developed. He complained of easy fatigability and dyspnea on slight exertion. His mother had noted that his face was always unusually flushed. Nosebleeds had occurred quite frequently.

The physical examination at this time revealed no marked enlargement of the heart. A systolic murmur was present and heard best in the third left interspace along the border of the sternum. The murmur was transmitted toward the apex and upward toward the base. The blood pressure was not taken at that time. A diagnosis of possible early involvement of the mitral valve was made. On roentgen examination the size of the heart was found to be from midline to right border, 42 cm, from midline to left border, 76 cm, total transverse diameter of chest, 218 cm. The heart was globular, was slightly enlarged, and suggested the early changes caused by mitral regurgitation. Reexamination of this film at a later date revealed a slight but definite scalloping of the under surfaces of the upper ribs. Tonsillectomy was advised because the tonsils were enlarged and apparently diseased. The boy was seen again during 1923. No change was noted in his heart. His tonsils had been removed and he had put on considerable weight.

He was reexamined in February, 1924, at which time it was noted that he had gained 17 pounds (77 Kg) since the previous examination. The heart was unchanged. The blood pressure was 150 systolic, 100 diastolic. The diagnosis was now changed to juvenile hypertension. A restriction in diet was advised in order to reduce his weight. By April, 1924, the second aortic sound was quite accentuated and a short systolic murmur had appeared over the aortic area. The blood pressure was 135 systolic, 90 diastolic. An attempt was made to obtain the blood pressure in the legs but this was unsuccessful, no sound coming through at any time. Fluoroscopic examination showed moderate enlargement of the heart, the contour suggesting a first degree hypertension heart.

In 1925 the boy began to complain of his legs "going to sleep," especially the left leg. Examination of the heart showed no change. The blood pressure was the same. Later in the year he began complaining of buzzing in the ears and tiredness of the legs. He appeared unusually well and was not incapacitated in the least by his cardiac condition. Roentgen examination at this time showed the dimensions midline to right, 47 cm, to left, 89 cm, total transverse diameter of chest,

From the Lymanhurst School Heart Clinic and the University of Minnesota Medical School Department of Medicine.

¹ Hamilton W F, and Abbott Maude E. Coarctation of the Aorta of the Adult Type. *Am Heart J* 3: 381 (April) 1928.

23.2 cm. The heart by this time, at the age of 9, had taken on the characteristic boot shape of a "hypertension" or "aortic" heart. The scalloping of the ribs was more marked than on the first film.

The patient did not report to the clinic again until April, 1932, seven years later, at the age of 17, when he came to obtain permission to play football. He had been attending school regularly and offered no complaints voluntarily. On questioning, however, he admitted that he had been having dizzy spells, noises in the ears, frequent nosebleeds, pain in both knees, and tiredness of the legs. He stated that his legs often "went to sleep." He had developed into a robust, quite obese, unusually healthy-looking young man. His face was flushed, his body was well developed, and there was no disproportion between his arms and his legs. Marked pulsation was noted in the episternal notch and in the vessels of the neck. On close inspection, definite pulsation was detected in the superficial blood vessels of the interscapular region. The pulsating vessels could be palpated with the fingers in the intercostal spaces. On each side of the spine in the interscapular region a rather rough "hemic type" of murmur could be heard. The heart was enlarged downward and to the left. A systolic murmur was heard along the left border of the sternum and over the aortic area. The second sound was accentuated and snappy. The blood pressure in the right arm was 178 systolic, 100 diastolic, left arm, 170 systolic, 100 diastolic. The blood pressure was again unobtainable in either leg and no pulsating vessels could be palpated in the popliteal spaces nor could pulsation in the dorsalis pedis be noted. In order to demonstrate the difference in magnitude between the pulsation in the vessels of the upper and lower extremities, an attempt was made to obtain polygraphic tracings of the vessels of the lower extremities, but this was unsuccessful. On running the hand over the surface of the body a decided drop in temperature was noted about the waist line. This was especially marked over the entire left buttock. Thermocouple skin temperature determinations showed a difference of 57 degrees C between the temperature of the skin over the left shoulder as compared to the skin over the left buttock.

On fluoroscopic examination the heart was found to have enlarged since the previous roentgen study and now had the contour of a "second degree hypertension" heart. The ascending aorta was dilated and pulsated markedly to the right of the sternum. This pulsation stopped rather abruptly and was not visible to the left of the sternum. The normal aortic knob was not present.

The examination of the eyegrounds showed no evidence of any hypertensive changes or any other abnormalities. The electrocardiogram revealed a sinus arrhythmia and a slight widening of the QRS (0.10 sec.), otherwise it was negative. The basal metabolic rate in this case was normal. Because of the increased blood supply to the upper part of the body, coarctation of the aorta has been mistaken for hyperthyroidism and some patients have been operated on.

Roentgen examination of the heart at this time revealed the dimensions midline to right 5.4 cm., to left 10.8 cm., total transverse diameter of chest, 30.0 cm. The shape was that of a "second degree hypertension" heart and no aortic "knob" was visible. The aorta was not seen to the left of the sternum. The scalloping of the ribs had now become quite marked and definite areas of erosion could be detected in the under surfaces of the upper ribs. A special film of the ribs reproduced here-with shows this particularly well.

COMMENT

It has been of considerable interest to watch this case gradually develop over a period of ten years. The first diagnosis made was that of early mitral disease, which was soon changed to juvenile hypertension. The correct diagnosis of coarctation of the aorta was not made until years later. Rarely is this diagnosis made until adulthood. Many cases are discovered at the postmortem table after a sudden and unexplainable death in an apparently healthy young person.

These patients, as in the present instance, often present a picture of unusually good health. They are well developed and have a high color to the face as the result of the increased blood supply to the upper part of the body. They commonly do very well in scholastic work, possibly, as Dr. Abbott has suggested, because of the oversupply of blood to the brain. My patient is a very good student. Enlargement of the heart, especially of the left ventricle, is quite common but may not be present. The case reported here presents more and more enlargement, especially of the left ventricle. While valvular lesions often accompany coarctation of the aorta, this patient probably does not have any disease of the valves. The murmur heard along the left border of the sternum, over the aortic area and on each side of the vertebral column posteriorly is probably transmitted from the point of constriction of the aorta. The increased blood supply to the head is evidenced by the

Erosion and scalloping of ribs at the age of 17 years

marked pulsation in the vessels of the neck, the plethoric appearance of the face, the occasional attacks of buzzing in the ears and dizziness. On the other hand, the undersupply of blood to the lower extremities accounts for the "going to sleep" and tiredness of the legs as well as the coldness of the lower part of the body. In the majority of cases of coarctation of the aorta, symptoms do not occur until some intercurrent infection occurs which weakens the myocardium or until some sudden strenuous exertion so increases the hypertension in the upper part of the body as to cause a rupture either of the aorta or of the heart itself or of one of the collateral blood vessels.

Abbott has divided patients with coarctation into three types: (a) those in whom the condition remains latent throughout life, (b) those in whom a sudden unexplainable cardiac decompensation occurs in the prime of life, and (c) those who have symptoms of cardiac embarrassment from the very beginning.

The physical manifestations in my patient are quite characteristic and the diagnosis should have been made at the age of 9 years. This boy presents the hyperten-

sion of the upper extremities, the lowered blood pressure of the lower extremities, definite evidence of collateral circulation in the upper thorax, and erosion of the ribs at the early age of 7.

As in the present instance, coarctation of the aorta is often mistaken for juvenile hypertension. All cases of hypertension in children should be suspected of coarctation. An early diagnosis is important in order to protect these young people from undue exertion.

PRIMARY TUBERCULOSIS OF THE PERICARDIUM

WILLIAM P. THOMPSON, M.D.
NEW YORK

One occasionally encounters a disease entity that is recognized and accepted by pathologists but is only vaguely known to clinicians. This appears to be true of primary tuberculosis of the pericardium. A review of the reported cases and an analysis of the several cases of this disease that have come to autopsy in this hospital revealed the fact that with only one exception (case 25) the clinical diagnosis at the time of death was recorded as "chronic myocarditis." In addition, this review brought out the fact that all these patients presented a rather surprisingly uniform and distinctive clinical picture, suggesting that the correct diagnosis might be made if the clinical features were known. It is with this in view that this paper is presented.

For the purpose of classification, tuberculosis of the pericardium may be divided into four main groups.¹

1 The tuberculous pericarditis may be part of a generalized tuberculous process.

2 It may be associated with a tuberculous polyserositis.

3 It may result from direct extension and rupture of adjacent tuberculous foci.

4 It may, as far as one can judge at autopsy, be either the only or the oldest tuberculous lesion.

The last group is known as primary tuberculous pericarditis.

Primary tuberculosis of the pericardium is known to pathologists as a moderately common pathologic entity. It occurs usually without other demonstrable tuberculous lesions, occasionally with a terminal miliary dissemination. These cases present the so-called bread and butter pericarditis appearance at autopsy. The pericardial sac is obliterated by a mass of tuberculous granulation tissue, which is most dense where it is attached to the visceral and parietal pericardium. The central zone between the two layers of shaggy granulations often contains a small amount of thick, blood-tinged fluid intermixed with necrotic, caseous debris. The opinion that this is a disease of elderly individuals is widely accepted by pathologists, and one finds such comments as "The pericardium is a frequent location for tuberculosis in the aged and in these cases it often occurs without other evidence of tuberculosis."² "This case illustrates the frequent occurrence in elderly males of pericardial tuberculosis unassociated with other tuberculous lesions."³ "The occurrence of pericardial tuberculosis in the aged without active tuberculosis else-

where is not uncommon."³ "The oldest tuberculous lesion in this case appears to be in the pericardium. As in the majority of cases observed here and elsewhere, the patient's age is well advanced."³ Attention is again called to the peculiarity of this lesion in the aged."⁴

REPORT OF CASES

CASE 1—In 1892, Virchow⁵ briefly reported the case of a man, aged 80, dying of rapidly progressive cardiac failure. Autopsy revealed tuberculosis of the pericardium without other tuberculous lesions.

CASE 2—In an analysis of seventeen cases of tuberculous pericarditis that came to autopsy, Osler⁶ reported an instance of primary tuberculous pericarditis occurring in a man, aged 52. There was a four months history of progressive cardiac failure with increasing dyspnea and terminal edema.

CASE 3—Meltzer⁷ reported a case of primary tuberculous pericarditis found at autopsy, in a man, aged 58, dying of a "sudden" heart failure.

CASE 4 (Fromberg⁸)—A woman, aged 71, with "progressive myocarditis," showed primary tuberculosis of the pericardium at autopsy.

CASE 5 (Marecaux⁹)—A man, aged 57, with "progressive cardiac insufficiency," died five weeks after the onset of symptoms. Autopsy revealed primary tuberculous pericarditis.

CASE 6 (Noscov¹⁰)—A man, aged 66, with a one month history of increasing dyspnea, presented at autopsy primary tuberculosis of the pericardium.

CASE 7—A differential diagnostic case was reported by Dr. Cabot¹¹ of a man, aged 80, with a three months history of progressive cardiac failure. The clinical diagnosis was "arteriosclerotic heart disease," the autopsy diagnosis, "primary tuberculous pericarditis with terminal miliary dissemination."

CASE 8 (Renaud and Chatagnon¹²)—A woman, aged 55, had symptoms of rapidly progressive heart failure. The heart appeared enlarged on percussion, the sounds were distant. Autopsy revealed tuberculosis of the pericardium without other lesions.

CASE 9 (Alston¹³)—A man, aged 70, had a two months history of increasing dyspnea. Examination revealed an enlarged heart with feeble sounds. He failed to respond to treatment and became progressively more decompensated and died. The clinical diagnosis was "chronic myocarditis," at autopsy the diagnosis was "primary tuberculosis of the pericardium."

CASE 10—Rawls¹⁴ reported a similar case occurring in a Negro, aged 51, who had a four months history of progressively increasing dyspnea and moderate substernal oppression.

CASE 11—Roubier and Langeneux¹⁵ reported the case of a woman, aged 62, who died one month after the onset of progressive dyspnea. She had an enlarged heart and poor heart sounds. The clinical diagnosis was "chronic myocarditis," the autopsy diagnosis, "tuberculosis of the pericardium." There was no other evidence of tuberculosis.

CASE 12—The same authors¹⁵ report a similar case in a man, aged 73, with a "short" history of increasing dyspnea. The heart was enlarged and the sounds were distant. "In spite of rest and digitalis, he became rapidly worse and died of cardiac failure two weeks after admission." The clinical diagnosis was "chronic myocarditis," the autopsy diagnosis, "primary tuberculosis of the pericardium."

3 Pappenheimer, A. M. Final note in autopsy protocol

Roubier and Dubois,⁴ in reviewing 1,300 autopsies, found 5 cases of primary tuberculosis of the pericardium without other tuberculous lesions. They call attention to the fact that the youngest of these patients was 67 years of age and stress the peculiarity of this lesion in elderly persons. The clinical features are given only in outline, but the authors suggest the possibility of making an antemortem diagnosis.

CASE 13—A woman, aged 84, had progressive heart failure.

CASE 14—A man, aged 77, had progressive heart failure

CASE 15—A woman, aged 67, had progressive heart failure and fever

CASE 16—A man, aged 73, had progressive heart failure and fever

CASE 17—A woman, aged 67, had progressive heart failure and fever

Mouisset and Bouchut¹⁰ report two cases

CASE 18—A mason aged 73, came to the hospital with a two weeks history of cough, increasing dyspnea and a severe cardiac oppression. His heart sounds were muffled, but the heart was not enlarged on percussion. In spite of rest, sedatives and digitalis, he grew progressively worse, edema appeared and he had a persistent unexplained fever of between 38 and 39 C (100.4 and 102.2 F). He died two months after the onset of symptoms. Autopsy revealed tuberculosis of the pericardium.

CASE 19—A man aged 71, came to the hospital with a three weeks history of progressive dyspnea and a sense of precordial oppression. The heart sounds were distant and weak, the rhythm irregular. His temperature during his stay in the hospital remained elevated, ranging from 36 to 38 C (96.8 to 100.4 F). In spite of rest, sedatives and digitalis he grew progressively worse and died. Autopsy revealed tuberculous pericarditis with a moderate right hydrothorax.

Mouisset and Bouchut comment thus on the clinical courses of their two patients "In the elderly, tuberculous pericarditis appears without localizing signs. In considering the diagnosis we recall the clinical importance of the recent inception of cardiac insufficiency. In these cases in spite of rest in bed in spite of milk diet, in spite of administration of diuretics and cardiac stimulants, the state of the patient does not ameliorate."

Audibert and Olmer¹⁷ report two cases of this disease in both of which the pathologic manifestations were similar to all the preceding cases and no other tuberculous lesions were found.

CASE 20—A man aged 49 had progressive heart disease

Case 21 — An elderly person" had progressive cardiac failure.

From the careful observations of these two cases Audibert and Ollmer discuss the symptoms, physical signs and clinical course of this disease suggesting the possibility of making the diagnosis. As their paper is the only one that has been found in which the clinical features have been stressed, their comments are presented in detail.

The onset of this disease is according to these authors insidious and occurs in patients who have no previous cardiac background. There is no history of rheumatic fever, syphilis or arteriosclerosis. The first symptoms are weakness, anorexia and slight loss of weight. These are shortly followed by the appearance of cardiac failure with dyspnea first only on exertion and later at rest and a sense of precordial constriction and heaviness. These symptoms progress rapidly and the patients seek admission to the hospital within a few weeks of the onset.

On physical examination these authors stress the four following cardinal signs

- 1 Dyspnea
2 Increase in cardiac dullness
3 Fever
4 General appearance of weakness The patients appear pale, tired and chronically ill

In addition, it is found that

- 1 The heart sounds are distant and muffled
- 2 There is often a mild cough
- 3 There is moderate progressive edema
- 4 The liver is enlarged

Examination of the heart by x-rays reveals cardiac enlargement

The course of these patients in the hospital is, according to these authors, quite uniform. The disease progresses rapidly, without remission and without response to treatment, to a fatal termination within a few months of the onset of symptoms.

They conclude that the diagnosis of primary tuberculous pericarditis should be very seriously considered

- 1 In a cardiac patient whose dyspnea progresses relentlessly without ever receding
- 2 In a cardiac patient who has a persistent unexplained fever
- 3 In a feverish cardiac case that progresses without remission to a fatal termination six or eight months after the onset of symptoms

During the past sixteen years, seven cases of primary tuberculous pericarditis have come to autopsy in the Presbyterian Hospital

CASE 22—A Bohemian laborer, aged 54 entered the medical wards with a two months history of rapidly increasing dyspnea on exertion. There had been no previous cardiac or respiratory symptoms. He stated that he had never had any of the symptoms of rheumatic fever but admitted having had a chancre as a young man. His present illness began suddenly and unexpectedly, two months before he came into the hospital, with shortness of breath on exertion. This increased persistently until admission and during the week before admission there had been increasing edema of the feet, legs and abdomen. Physical examination revealed that he was well developed and well nourished, and had obvious cardiac insufficiency. There was moderate orthopnea and considerable cyanosis. There was pitting edema of both legs and a distended abdomen, obviously containing fluid. The heart was enlarged to the right and left, there was no widening of the base. The heart sounds were described as very distant and faint. The rhythm was regular, with a rate of 110, no murmurs were heard. The pulse suggested pulsus paradoxicus. Death occurred twelve hours after admission. The only temperature taken was 99.2 F. At autopsy the pericardial cavity was found to be entirely obliterated by an old, long-standing process which on section presented large amounts of tuberculous granulation tissue and a wide caseous area. The heart muscle itself was normal. There was chronic passive congestion of various viscera. Dr R A Lambert made the following final note, summarizing the case. The presence of such an extensive tuberculous pericarditis without primary focus elsewhere is interesting. Dr Pappenheimer tells me however, that he has seen several such cases in individuals of middle age or older and that there are a good many cases of this sort reported in the literature."

CASE 23—A Chinese laundryman aged 57 came in with a three months history of progressive dyspnea on exertion and progressive swelling of the legs and abdomen. There was no previous history of cardiac or respiratory symptoms, there was no suggestion of rheumatic fever or syphilis in the past. Examination revealed an obvious cardiac insufficiency. There was moderate orthopnea and slight cyanosis with marked edema of the legs and an enlarged abdomen obviously containing fluid. The heart was described as being considerably enlarged.

the rate varied between 100 and 110, the rhythm was regular. The sounds at the apex were muffled and distant, there were no murmurs. The pulse was described as being very soft but otherwise normal. During his ten days in the hospital he became steadily worse, in spite of sedatives and digitalis. During this period his temperature was always elevated, ranging from 99 to 100 F, with one spike to 102.5. At autopsy, the heart and pericardium were identical with those in the previous case. Although several scattered tubercles were found in various organs, the pathologist felt that these represented a recent dissemination and that the primary lesion was in the pericardium.

CASE 24—A man, aged 79, American, a caretaker, came to the hospital with a history of increasing dyspnea on exertion and increasing swelling of the legs and abdomen of three months duration. There were no previous cardiac or respiratory symptoms, there was no suggestion of rheumatic fever or syphilis. Examination revealed an obvious cardiac insufficiency. There was moderate orthopnea but no cyanosis. There was moderate edema of the lower extremities. The heart was described as being greatly enlarged, the rhythm was totally irregular, the rate varied between 80 and 110, the sounds at the apex were barely perceptible. In spite of the usual cardiac therapy, he failed rapidly and died five days after admission. During those five days, his temperature varied between 99 and 100.2 F. At autopsy, lesions identical with those in the previous cases were found, and there was a terminal miliary tuberculosis of the liver, lung and spleen. Again the pathologist felt that the oldest lesion was in the pericardium.

CASE 25—An Irish watchman, aged 53, entered the hospital with a ten days history of increasing dyspnea and weakness. His past history was irrelevant, and there had been no previous cardiac symptoms. Examination revealed only slight dyspnea. There was no edema and no cyanosis. The heart was enlarged, the rate varied from 80 to 100. At first the rhythm was regular, but auricular fibrillation developed shortly after admission. The heart sounds were described as being distant. The patient remained in the hospital fourteen weeks. During this time he had a persistent, irregular fever, never below 99 and never above 103 F, for several weeks remaining between 99 and 101. During this entire time the symptoms of cardiac insufficiency progressed without remission, and he died sixteen weeks after the onset of his sickness. During this entire time the etiology of the progressive cardiac failure was obscure. Several weeks after admission a definite pericardial friction rub was heard and this suggested, together with the patient's course, the possibility of tuberculous pericarditis. At autopsy, lesions identical with those in the previous cases were found. Dr Pappenheimer's final note read "This case illustrates the frequent occurrence in elderly males of pericardial tuberculosis unassociated with other tuberculous lesions."

CASE 26—An American housewife, aged 62, came into the hospital with a two weeks history of rapidly increasing dyspnea and edema. There had been no previous cardiac or respiratory symptoms. Examination revealed an obvious cardiac distress. There was moderate orthopnea and cyanosis and tremendous edema of the abdomen, legs and back. The heart was moderately enlarged, the rate 90, the rhythm regular. The patient died three days after admission. During these three days, her temperature had remained at 101 F. Autopsy revealed, in addition to lesions identical with those seen in the previous cases, moderate general arteriosclerosis. Dr Pappenheimer's final note read "The occurrence of pericardial tuberculosis in the aged without active tuberculous lesions elsewhere is not uncommon."

CASE 27—A man, aged 70, Bohemian, an upholsterer, came in with a one year history of cough, loss of weight and fever, and increasing dyspnea on exertion. He was cachectic and chronically ill. There was evidence of pneumonic consolidation in both lower lobes. The prostate was hard and irregular, the heart was described as being enlarged and regular, the rate was 120, the heart sounds were moderately distant. The most probable diagnosis was thought to be carcinoma of the prostate with metastasis. He grew rapidly weaker and died ten days after admission. During this period, his temperature varied

between 99 and 103 F. His pulse remained between 110 and 120. At autopsy, many tuberculous lesions were found, including tuberculosis of the pleura, pericardium and genito-urinary tract. There was a terminal acute generalized miliary tuberculosis with tuberculous meningitis. Dr Pappenheimer's final note read "The oldest tuberculous lesion in this case appears to be in the pericardium. The picture here follows the rule in being unassociated with active pulmonary lesion, aside from the terminal miliary seeding. As in the majority of cases observed here and elsewhere, the patient's age is well advanced. The genito-urinary tuberculosis appears to have originated in the left epididymis and to have extended up the lumen of the vas deferens to the seminal vesicles and prostate. The generalized miliary tuberculosis is obviously of short duration, as is the meningitis, from the structure of the lesions, probably not older than one-two weeks. There is a very extensive but recent lobular pneumonia. Probably this latter is the immediate cause of death."

CASE 28—A German watchman, aged 65, came to the hospital with a two weeks' history of increasing dyspnea on exertion. He had also felt feverish during this time. There had been no edema. There was no history of previous cardiac or respiratory trouble. He had never had syphilis or rheumatic fever. On examination he appeared chronically ill, with moderate orthopnea. The heart was enlarged, the rhythm totally irregular, the rate varying between 100 and 120. The heart sounds were described as being very distant and of poor quality. There were no murmurs. He failed to improve on rest and digitalis and died ten days after admission, of cardiac failure. During these ten days his temperature varied between 100 and 102 F. At autopsy an old adhesive caseous tuberculous pericarditis was found, identical with those in the preceding cases.

In none of these cases was any significant abnormality noted in the blood pressure.

COMMENT

In many of the foregoing cases, adequate clinical information is lacking. However, in those reports in which this information is available and in my series of seven cases, the clinical picture of patients presenting primary tuberculosis of the pericardium at autopsy is surprisingly consistent and uniform. Audibert and Olmer,¹⁷ in their comments on the clinical aspects of their two patients, present the outstanding clinical features of this disease. Their criteria for diagnosis seem to be confirmed by the other cases. Their failure to stress the advanced age of these patients is explained by the fact that one of their patients was the youngest in the entire series.

The clinical picture presented by these patients is so consistently uniform that it seems as if a correct ante-mortem diagnosis should be made, provided the clinical features of this disease are known and the pathologic condition is suspected.

Certain points seem to occur with striking regularity throughout this entire group.

1 The age of the patients is well advanced, the youngest in the series being 49, the oldest 84, and the average 69.5 years.

2 The onset is insidious and occurs in patients without previous history of cardiac symptoms or evidence of previous rheumatic fever, syphilis or arteriosclerotic heart disease.

3 There is a presence of unexplained fever in all cases.

4 There is a rapidly progressive increase in the symptoms of cardiac insufficiency proceeding relentlessly to a fatal termination within a very few months of the appearance of the first symptom. "It is precisely

this rapidly fatal evolution and this striking failure to respond to treatment that identified this disease"

SUMMARY

1 Twenty-eight cases of primary tuberculosis of the pericardium, including seven of my own, present a uniform and characteristic clinical picture

2 The following points are of considerable diagnostic importance and should force one to consider this diagnosis the presence in (a) elderly individuals, of (b) cardiac failure, otherwise unexplained, which progresses relentlessly, without ever receding or responding to treatment, to a fatal termination within a very few months, and is associated with (c) a persistent, unexplained fever

NELSON PAUL ANDERSON, M.D.

LOS ANGELES

Since our recognition several years ago of the presence of *Demodex folliculorum* in the majority of our patients with acne rosacea and an allied condition which we have designated as pityriasis folliculorum (*Demodex*), our therapeutic results have been far superior to those obtained by the usual treatment of acne rosacea

In view of the fact that Kaufmann-Wolf¹ called attention to the frequent occurrence of *Demodex folliculorum* in the pustules of acne rosacea as long ago as 1925, it seems rather surprising that so little recognition has been accorded this valuable contribution. In fact, within the past few months Stokes and Beerman² have published an exhaustive study of the etiology of acne rosacea especially from an emotional and nervous point of view without making any mention whatever of *Demodex* as a possible factor

One might argue that, because *Demodex* is a more or less "normal" inhabitant of the human skin, it is without etiologic significance. Granting that the organism may be found on apparently normal skins, it usually is present in small numbers and may be found only by expressing sebum from some of the oil glands by pressure. This is in striking contrast with the large numbers of *Demodex* that can easily be found in many cases of acne rosacea, it is not uncommon to find ten or fifteen organisms in a single tiny follicular scale or superficial pustule. It would be just as fallacious to say that, because the staphylococcus is found on many healthy skins, it is without any causal relation to furuncles or carbuncles.

In two previous communications we³ have called attention to the frequent occurrence of *Demodex* in

acne rosacea and in pityriasis folliculorum (*Demodex*), a newly described clinical entity which is probably closely related to acne rosacea. Lawrence⁴ has recently confirmed the latter observation. On the other hand, we have been able to find *Demodex* only rarely in the pustules of acne vulgaris.

Our reasons for regarding *Demodex folliculorum* as an etiologic factor of importance in these two disorders are as follows:

1 The organism is easily found in from moderate to large numbers in pus from superficial lesions or in the dry follicular scales, whereas it is usually absent in acne vulgaris.

2 A rapid clinical improvement or cure follows the application of strong antiparasitic applications and the daily use of soap and water.

Fig. 1.—Typical severe acne rosacea of one year's duration. *Demodex folliculorum* was found in moderate numbers in pus from superficial lesions. Gastric analysis revealed moderate reduction of acidity.

3 Accompanying the clinical improvement there is a corresponding decrease in the number of *Demodex folliculorum* organisms that can be isolated from the skin.

Since the publication of these earlier reports, a total of seventy-seven patients in private practice have been seen who have presented the clinical picture of acne rosacea or pityriasis folliculorum (*Demodex*). The same conclusions that have been mentioned are applicable to this larger series. On these patients, fifty presented typical cases of acne rosacea. During the same period of time that these cases were collected, only thirteen cases of acne rosacea were seen which failed to reveal *Demodex folliculorum*. The accompanying table gives a summary of our observations.

It will be noted that a considerable proportion of the patients used soap and water infrequently or not at all. It is felt that the excessive use of cold cream and powder and the substitution of cleansing cream for soap and water favor the development and multiplication of these

Fig 2—The same patient after three applications of Danish ointment. This photograph was taken exactly one week after the preceding picture, no other medication was used

organisms. This may partially account for the recognized predominance of acne rosacea in women. With all respect to the interesting paper of Stokes and Beerman, we do not feel that it is necessary to search so widely for the cause of this condition in most cases. A small droplet of pus obtained from a superficial pustule the size of a pinhead, placed on a glass slide and macerated with a drop of 40 per cent potassium hydroxide or glycerin, will usually show under the microscope from one to fifteen or more organisms. Usually the contents of two or three pustules are examined, or in those cases in which the complaint only of dry, rough skins is made, some of the minute dry follicular scales are picked off and examined in the same manner.

When such an examination shows the presence of *Demodex folliculorum*, local treatment alone will usually effect an improvement that is almost unparalleled in dermatologic therapy. Until recently we have employed an ointment such as is used for the treatment of scabies: betanaphthol, 2 Gm., sublimed sulphur, 4 Gm., balsam of peru, 15 Gm., petrolatum, 15 Gm. In spite of the fact that many of these patients have declared that their skin was so delicate that they could not even tolerate soap and water, we have obtained excellent results usually within from one to three weeks. The patient is instructed to wash thoroughly with soap and water every night and to apply the ointment for only three nights. There is usually a temporary increase of redness with some desquamation immediately following the

application of the ointment, which, however, subsides in several days. It is usually necessary to have the patient repeat the ointment once or twice a week for several weeks. There have been but few recurrences in our series of cases, and those which have recurred have been rather mild and have responded promptly to further treatment.

More recently we have used Danish ointment in the same manner with equally good results and with less irritation.

Observations in Seventy-Seven Patients*

	Acne Rosacea	Pityriasis Folliculorum	Total
Male	8	1	77
Female	42	26	
Little or no soap	25	20	45
Soap daily	12	4	16
Use of soap not stated	13	3	16
Gastro intestinal symptoms	23	8	31
Low gastric acidity	12	0	12
Normal gastric acidity	6	2	8
Cure or marked improvement within three weeks	29	18	47
Cure or marked improvement in from three to six weeks	16	3	19
Result not stated	3	5	8
Not improved	2	1	3
Recurrence recorded	10	3	13

* In these patients, *Demodex folliculorum* was found either in the follicular scales or in the superficial pustules in from moderate to large numbers. In some cases as many as fifteen organisms were found in a single low power microscopic field. All of these patients were treated by strong antiparasitic ointments locally. In only a few instances was any additional treatment used, such as x-rays or hydrochloric acid by mouth. The presence or absence of gastro intestinal symptoms was not recorded in all cases, of those listed, it was frequently of a minor nature.

We do not feel that the improvement is due to the effect of sulphur on the seborrhea, because some of the most striking results occur in those cases presenting dry skins and with no evidence whatever of seborrhea. The scaling mentioned in cases of pityriasis folliculorum is not of a seborrheic type but rather consists of fine dry

Fig 3—*Demodex folliculorum* (high power magnification of a specimen in 40 per cent potassium hydroxide)

inconspicuous white scales about the mouth of the sebaceous ducts or the base of the lanugo hairs, resembling the frosting resulting from an ethyl chloride spraying. Microscopic examinations of the contents of pustules or scales made on each visit show a progressive diminution in the number of parasites until no more

pustules or scales are available, which often occurs after the second or third week.

Of course, those patients who do not show *Demodex* must be treated according to the local and systemic indications in each case and undoubtedly a few of the cases with *Demodex* infection may need supplementary treatment, directed to the nervous system, gastrointestinal tract, and so on.

CONCLUSIONS

1 In seventy-seven cases of acne rosacea and pityriasis folliculorum (*Demodex*), *Demodex* folliculorum was found in superficial pustules and follicular scales in from moderate to large numbers.

2 In sixty-nine of these patients whose results could be followed, striking clinical improvement or cure was obtained in all but three cases by the use of a strong antiparasitic ointment.

3 Out of sixty-three cases of typical acne rosacea seen during the past two years, in which examination for *Demodex* folliculorum was made, the organism was found in fifty cases. With the exception of three patients who did not return for observation, excellent results were obtained in all but two of these cases by the use of a strong antiparasitic ointment without any other treatment.

4 Irrespective of any argument concerning the causal relationship of *Demodex* folliculorum to acne rosacea, the fact remains that local antiparasitic treatment as described has given clinical results far surpassing anything in our experience with this disease.

THE USE OF THE DRINKER RESPIRATOR IN THE AFTER-CARE OF INFANTILE PARALYSIS

ARTHUR T. LEGG, M.D.

BOSTON

The use of the respirator in the acute stage of infantile paralysis has saved the lives of many patients with respiratory involvement.

Not only was the mortality of infantile paralysis with involvement of the muscles of respiration much greater before the invention of this machine but many of those who survived died subsequently with some lung disease resulting from diminished aeration.

In the after-care clinic of the Harvard Infantile Paralysis Commission, we have seen a considerable number of the patients who have survived this type of the disease and we have been impressed by the marked depression deformities that have developed in the chests of those who have not recovered the power of voluntary expansion of the chest.

The exact type of the deformity depends on the location and extent of the paralysis of the muscles of respiration. It is fairly common to find breathing carried on by the diaphragm with practically no expansion of the chest taking place on either side as a result of bilateral paralysis of the intercostal muscles. This in time produces a general depression of the chest which may be accentuated in the lower region if the patient has been allowed to sit unsupported in a slumped position. Greater weakness of the diaphragm and intercostals on one side of the chest results in an asymmetrical depression which suggests the flattened chest resulting from a collapsed lung. Loss of function in

the pectoral and sternocleidomastoid muscles also tends to increase the sunken appearance of the upper part of the chest, while some lower rib motion may be maintained by the diaphragm, with or without the help of the lower intercostal muscles. It is often difficult to estimate exactly the amount of motion produced by the different muscles, for strong action of the diaphragm produces motion of the lower ribs.

Having seen these patients with deformed chests and having seen demonstrated what the respirator would do in the acute stage, I conceived the idea of using the respirator as an exerciser after the need for its use to maintain life had passed.

The prevention of fatigue is one of the most important factors in the after-treatment of muscles affected by infantile paralysis, and this aspect of its use has been considered, for it produces chest expansion and breathing without muscular effort. The action is entirely passive motion, without fatigue. The value of rest and

Fig. 1—Contracted chest with depressed sternum following intercostal involvement five years before.

Fig. 2—Contracted chest following intercostal involvement six years before.

the prevention of contractures in other paralyzed muscles are recognized, and there seems no reason why the same principles should not hold good for the muscles of respiration.

Measurements of voluntary expansion of the chest, taken on a series of patients who received regular daily treatment in the respiration machine over a period of months showed a definite and steady increase from amounts under one-half inch up to two and three inches of voluntary expansion away from the machine. It was noticeable that this expansion was produced mainly by the intercostal muscles as in a normal person, without the excessive use of the accessory muscles of respiration such as the sternocleidomastoids, which, if present were very strikingly used at first.

From a medical standpoint, the increased aeration of the lungs and the deeper movement of the diaphragm in the abdominal cavity resulting from the use of the

feeling-discharge But as more and more these projections are deprived of their artificial feeling-content through the application of a technic which acts as a constant barrier to the passage of social affects along these habitual channels of interideational exchange, to the same degree these partitive affects become reassimilated within the patient's organism as total reactions¹⁰ In this way, feelings that were the expression of a sheer misplacement of the organism's integral sensations now operate in support of the organism as a total process

In the case cited, therefore, all interventive measures were reduced to the single unitary aim of restoring those reactions of the patient which, having become physiologically deflected, tended habitually to clutter the symbolic, cerebral avenues of interchange Our corrective measures were centered toward redirecting these deflected tensional alterations into the systemic paths of reaction which belong to the organism as a whole No effort whatever was made in the direction of altering the patient's ideas, illusions, references, ruminations or other "mental" symptoms, yet the patient's adjustment to his mental and social environment has been completely transformed While the sole focus of interest was directed toward the patient's internal tensions and skews, yet the corrective results were straightway registered in the sphere of his external adaptation He is now entirely free of his former projected concern as to his father's or any one else's ideas or projections in regard to him He has resumed interest in his studies, and his whole subjective attitude toward all his presumably subjective "symptoms" has become converted into a clear objective sense of their underlying physiologic meaning within him¹¹ The emphasis, then, of our altered position is an emphasis on the physiology of the interreactions which occur within the organism, individual and phyletic, as contrasted with those interreactions which are purely interideational or mental

Holding to a consistent laboratory attitude and directing our observations toward the interreactions occurring currently among individuals composing social groups, it was found that so-called mental disorder does not consist in a disagreement of ideas or of conduct between one individual and another, whether physician and patient, or father and son It was found that, while the symptomatology or outer appearances of mental disorder with its transference and resistance, its withdrawal or dependence, are always interindividual or social, the essential disorder does not consist in a disagreement between the thoughts or the ideas projected from the brain of the mentally ill individual as contrasted with the prevailing norm of ideas projected from the brains of a community of individuals These are merely the outer symptoms But, as is the case throughout the domain of medicine elsewhere, it was found that the disease from which the mentally disturbed patient suffers is circumscribed within his own body-processes and that this disease consists in a disagreement or disparity between a function of his own brain and that of his organism as a whole¹² The disorder is found to consist in a state of tension or alteration specific to the prosencephalic portion of a patient's organism in contrast to the general, systemic state of tension existing throughout his body generally The real disorder

consists in a physiologic conflict between the two species of attention or adaptation through which the organism is related to the external world—between those general internal tensional adjustments which relate the organism to the total object and those specific external tensional adjustments which relate the organism to the part representing the symbol of the object In brief, it has been found that the conflict is one between the physiologic tensions and strains pertinent to the partitive or cerebral mode of attention in contrast to the tensions and strains that belong to the organism's attention as a total, systemic function

As this altered physiologic approach gradually attains wider medical application, the physician who has hitherto treated ideas with ideas, will regard these ideas and interreactions of a patient as mere indicators of an underlying physiologic disorder within the patient's organism, and he will not seek to remedy these various arbitrary and unpredictable ideas and opinions as they exist socially within and about the patient¹³ However valuable these outer manifestations may be as aids in locating the true condition, the physician will no more attempt to treat a mental disorder by correcting the symptoms expressed in the patient's feelings or ideas than the stomach specialist would attempt to treat a patient for a disorder of the stomach by correcting the outer symptoms or sensations associated with it Like the stomach specialist, he will apply himself to the actual physiologic organism of the patient, and in doing so he will discover that the real disorder is not the patient's ideas in regard to himself nor his reaction to other people's ideas in regard to him In short, the physician will find that this conflict is not mental, social or interideational, but that it is physiologic He will find that tensional alterations, now symbolized as ideas and "emotions," have been artificially forced into the patient's cerebral system and that these physiologic alterations clash with and affront those organic tensions and reactions which pertain to the physiology of his organism as a total process¹⁴

In view of this physiologic disturbance in the tensional interrelations of the organism as a whole and of related structural manifestations, we must question the position of psychiatry toward mental impairments as being inconsistent with scientific procedure and therefore no longer tenable We must abandon the view that ideas are competent to remedy so-called mental disorders or that what are called mental measures of repair are applicable to what are called mental diseases From experimental studies covering many years in and with groups composed of normal and neurotic subjects, evidence is offered that the material that occupies the interest of psychiatry is not the material that constitutes the patient's disorder In short, our normal mental measures of repair, as they are now universally practiced, are without scientific basis for meeting the problem existing in those pathologic distortions of which we see only the outward signs and symptoms now characterized as "mental" disease

13 Burrow, Triggant The Social Basis of Consciousness London George Routledge & Sons, Ltd., and Kegan Paul Trench Trubner & Co Ltd New York Harcourt, Brace & Co 1927 pp 256, *Insanity a Social Problem*, Am J Sociol 32 80 87 (July) 1926

14 It is not at all realized how very small a percentage of mental conditions apart from those which have attained the stage of closed and inaccessible systematization ever reach the psychiatrist proper The mental conditions exist in the patients one finds in the offices of the general practitioner or even the dentist Such patients of course make ready contact with the Christian science healer with the theosophist and the chiropractors, not to mention the consultation rooms of the clergy of teachers, journalists social workers and others Indeed the clinical psychiatrist sees but an infinitesimal proportion of the masses of people who move in and out of our midst with definite symptoms of 'mental' disturbance

CONCLUSION

A laboratory study of man and his reaction as a total process gives indication that the false ideas, the delusions and phobias, the mood-alternations of elation and depression, the emotional conflicts, the repressions and overaccentuations characteristic of mental disease, all are but reflections of an impairment that is deeper seated within the organism. This impairment consists in tensions, alterations and disturbances that affect definite body processes. In a word, the conflict or disparity present in mental disorders consists in a discrepancy between those feelings and sensations which belong to the organism as a whole and those sensations which belong to that circumscribed segment of the organism located in the cephalic region with its secondarily acquired ideas and images. As this conflict consists in a disparity between two clearly defined body zones, it is a physiologic disparity. Such a condition is perceptible and remediable only through recourse to physiologic methods of repair and not through a program which attempts to exchange ideas for ideas and images for images.

NATHAN RAKIETEN, BS
J F FAZIKAS
DELAFIELD DU BOIS, BS
AND
E F GILDEA, MD
NEW HAVEN, CONN

The effect of alcohol on the acid-base balance has not been studied except by Thomas,¹ who noted a diminution of the carbon dioxide content and carbon dioxide capacity of the blood after the ingestion of alcohol. In the present investigation, the influence of alcohol on the p_{H} , carbon dioxide content and carbon dioxide capacity of arterial blood was determined in thirty dogs and twelve human subjects. The blood

TABLE 1—*Effect of Alcohol Ingestion on Blood Dextrose, Mg per Hundred Cubic Centimeters*

Subject	Dose of 10 per Cent Alcohol Cc per Kg	Before	After	1/4 Hr	1 Hr	2 Hr	7 Hr

pu value		41		7.20	7.23	7.25	7.31
Man	10	84	83		94	88	

samples were also analyzed for lactic acid, dextrose and alcohol. In the dogs blood was drawn from the femoral artery, and in the human subjects from the brachial artery. Both dogs and human beings were studied in the post-absorptive state and without narcotics other than the alcohol which was always given in 10 per cent solution. As a result of these studies it was found that alcohol produced an acidosis which was evident in changes of pH and carbon dioxide

capacity and content as well as of the lactic acid and dextrose concentration of the blood. The results on human beings and dogs were similar.

In eighteen out of twenty-one experiments on dogs and in all the human experiments the blood sugar rose. In a typical case (table 1) the dog was given 50 cc of 19 per cent alcohol per kilogram of body weight, and the increase in blood sugar was 28 mg per hundred cubic centimeters in two hours. One of the human subjects was given 10 cc of alcohol per kilogram of

TABLE 2—*Effect of Alcohol Ingestion on Lactic Acid, Mg per Hundred Cubic Centimeters*

Subject	Dose of 10 per Cent Alcohol Cc. per Kg	Before	After	$\frac{3}{4}$ Hr	$2\frac{1}{4}$ Hr	6 Hr
Dog	50	14			25	
Man	10	15	24	18	30	26

body weight The total amount of alcohol is the same as that contained in a tumblerful of whisky 100 proof One hour was required to drink the liquid At the end of that time the blood sugar had risen from 84 to 93 mg per hundred cubic centimeters, three fourths of an hour later it was 94 mg, and six hours after the ingestion of the alcohol the blood sugar had returned to 88 mg per hundred cubic centimeters

This increase in blood sugar is probably not due to a transformation of alcohol to dextrose. However, it is not unlikely that the tissues remove less dextrose from the blood, since alcohol may take the place of foodstuffs in supplying energy to the body. In addition to a diminished removal of dextrose from the blood there is probably a greater amount of that substance entering the blood stream. This may be due either to the narcotic effect of alcohol, which may diminish oxidations in the liver and thus permit the cleavage of glycogen and the formation of dextrose, or to the acidosis which favors the breakdown of glycogen to dextrose. The observations on dog 2 (table 1) reveal that the rise in blood sugar is accompanied by a fall in p_H .

Alcohol acts as a glycogenolytic agent not only on the liver glycogen, thus increasing blood sugar, but also on muscle glycogen, which is broken down to lactic acid and therefore increases the lactic acid content of the blood. A rise in blood lactic acid was found in ten out of seventeen experiments on dogs. For example, increases in lactic acid from 14 to 25 mg per hundred cubic centimeters in the dog and from 15 to 30 mg in the human subject are shown in table 2. This effect of alcohol may be explained as a result of insufficient oxidation in muscle, due perhaps to reduced blood flow and to an inhibitory effect on cellular respiration. It is well known that when oxidations are inadequate, lactic acid accumulates in muscle and is poured into the blood stream.

In the lactic acid content of the blood increases, the carbon dioxide capacity or alkali reserve might be expected to decrease, for the accumulated lactic acid would rob bicarbonate of its base, thus diminishing the amount of alkali available to combine with carbon dioxide. In each of twenty-four observations made in the course of eight experiments the capacity fell. In one dog (table 3) the carbon dioxide capacity starting at 45.4 volumes per cent fell to 34.5 in two hours and returned to 43.0 six hours later. In a human subject the carbon dioxide capacity started at 46.2 and

1. In the Department of Health and Human Services, the University
of California, there has been a meeting with the staff of
the Department of Health and Human Services, the American Medical
Association, and the American Dental Association. 41 x 189

decreased to 43.0 per cent at the end of six hours (table 3)

Decrease in blood capacity would be expected to liberate carbon dioxide from its union with base, thereby increasing the carbon dioxide held in solution by the blood. Ordinarily this sets into operation a

TABLE 3—Effect of Alcohol Ingestion on Carbon Dioxide Capacity of Whole Blood at 40 Mm Tension of Carbon Dioxide

Subject	Dose of 19 per Cent Alcohol, Cc per Kg	Before	After	1 Hr	2 Hr	6 Hr
Dog	50	45.4		40.9	34.5	43.0
Man	10	46.2	46.0	43.7		43.0

series of adjustments producing hyperventilation and eliminating the freed carbon dioxide. However, with the depression of the respiratory centers by alcohol, the usual adjustments for the elimination of carbon dioxide do not take place, and a rapid retention of carbon dioxide with a depression of the p_H occurs. The initial effect on carbon dioxide content of the blood was variable. In one experiment there was a transitory rise in carbon dioxide content, and in three others it remained unchanged in the first observation after the ingestion of alcohol. Ten other experiments disclosed a progressive diminution of carbon dioxide content.

TABLE 4—Effect of Alcohol Ingestion on Carbon Dioxide Content of Whole Blood, Volumes per Cent

Subject	Dose of 19 per Cent Alcohol, Cc per Kg	Before	After	¼ Hr	1 Hr	4 Hr	6 Hr
Dog	50	44.1		37.8	34.7	36.7	
Man	10	48.3	45.4		44.7		45.1

The final effects, however, were uniform, and in all the experiments the carbon dioxide content fell. In the dog (table 4) the content was lowest one hour after alcohol was taken, the decrease being from 44.1 to 34.7 volumes per cent. A human subject exhibited a decrease from 48.3 to 44.7. The carbon dioxide capacity or bicarbonate in one series of observations (table 5) fell during the first hour and a quarter after the ingestion of alcohol and the carbon dioxide content, after a minor decrease, returned toward the original value. One may infer from this fact that there are at least two factors influencing the blood, an early effect due to a depression of the respiratory centers, the retention of carbon dioxide in the blood, and a later one, resulting from the accumulation of lactic acid.

TABLE 5—Effect of Alcohol Ingestion on Carbon Dioxide Capacity and Carbon Dioxide Content, Volumes per Cent

Before	36.7	38.0
After ¼ hour	34.7	33.2
After ½ hour	32.4	36.1
After 1¼ hour	30.0	37.6

If sufficient carbon dioxide is eliminated through the lungs, the p_H should remain unaltered. On the other hand, if the volume of carbon dioxide liberated through the lungs is small in relation to the bicarbonate content of the blood and the fraction $\frac{CO_2}{NaHCO_3}$ increases in the blood, then there is a relative retention of carbon dioxide, the p_H decreases and an acidosis supervenes.

Determination of the p_H or hydrogen ion concentration of the blood seemed important. This was done in some instances by the colorimetric method of Hastings and Sendroy,² but most of the results were obtained by means of the glass electrode.³ A fall in p_H was observed in five of eight determinations made colorimetrically and in all six cases studied electrometrically. The p_H of one of the human subjects fell from 7.35 to 7.30 (table 6). Observations on the dog revealed a change in p_H greater than that in man, for the animal received a larger dose more rapidly by the stomach tube. This change occurred with great rapidity. In one case the p_H had diminished from 7.41 to 7.29 a quarter of an hour after the ingestion of alcohol, an hour later it had fallen to 7.22. It did not return to normal until the next day. The changes in p_H vary with those of the concentration of alcohol in the blood, the greatest fall in p_H occurring at the time when the

TABLE 6—Effect of Alcohol Ingestion on p_H of Whole Blood of Human Subject

	Before	After		
p_H	7.35	1 Hr	2 Hr	7 Hr
		7.30	7.31	7.35

concentration of alcohol in the blood is largest (table 7). The early rapid fall in p_H is probably due to inadequate pulmonary ventilation, for there is an accompanying increase in carbon dioxide content and no rise of lactic acid. On the other hand, as the alcohol content of the blood diminishes, its narcotic effect on the respiratory center also decreases and the p_H returns to normal despite the increased concentration of lactic acid. With the exception of the relative retention of carbon dioxide and the production of lactic acid, no other acid could be identified during the oxidation of alcohol. No trace of acetic acid could be detected in the blood even by the delicate lanthanum nitrate test of Kruger and Tschirch.⁴ Alcohol itself does not change

TABLE 7—Effect of Alcohol Ingestion on p_H and Alcohol Content of Whole Blood of Dog

	Before	After				
p_H	7.41	¼ Hr	1 Hr	2 Hr	7 Hr	24 Hr
		7.29	7.22	7.28	7.31	7.41

the p_H of the blood in vitro. A few determinations revealed no change in the total base or chloride content of the serum.

The entire picture produced by the ingestion of these large doses of alcohol may therefore be due to the narcotic action of this substance. The increase of blood dextrose and lactic acid occurs as a result of the action of alcohol on liver and muscle glycogen respectively, and the fall in p_H is due to the depression of the respiratory centers. This conception of the action of alcohol is not incompatible with the fact that alcohol in moderate doses may increase the respiratory volume and the metabolic rate. A distinction must be made between the primary and secondary effects of alcohol.

² Hastings, A. B. and Sendroy, Julius, Jr. J. Biol. Chem. **61**, 695 (Oct.) 1924.
³ Du Bois, Delafield. Science **76**, 441-443 (Nov. 11) 1932.
⁴ Krüger, D., and Tschirch, E. T. Mikrochemie **8**, 337-338, 1930.

Two of the primary effects of alcohol ingestion are a diminution in p_H and an accumulation of lactic acid in the blood. The presence of lactic acid is a stimulant to respiration and oxidation. Therefore, there is secondarily an increase in respiratory ventilation. However, not until all the alcohol in the body has been removed by oxidation is this increase in respiration sufficient to cause the p_H to return to its normal value.

From the clinical point of view it is well to remember that alcohol may be contraindicated when an acidosis already exists.

TABLE 8—Lactic Acid Content (Mg per Hundred Cubic Centimeters) of Arterial Blood of Patients Recovered from Alcoholic Coma

LACTIC ACID AND THE AFTER-EFFECTS OF ALCOHOL

After a prolonged alcohol debauch the lactic acid disappears slowly from the blood. There is only a gradual restitution of the original conditions. Nine individuals who had been drinking for several days had increased concentrations of lactic acid which endured, in one case, for several days. Table 8 shows the concentration of lactic acid in five patients. The high level of lactic acid after recovery from alcoholic coma is evident. In four cases the concentration of lactic acid was increased on the first day after admission and returned to normal resting values by the third day. The fifth patient still had an increased concentration of lactic acid four days after the ingestion of alcohol, on the tenth day lactic acid had returned to its resting value. Perhaps it is such changes that are responsible

Chart 1—Effect of alcohol ingestion on pH, carbon dioxide, lactic acid and alcohol contents of whole blood (experiment of Feb. 4-5, 1932)

for the so-called hangover after an alcohol debauch. It may be that the long continued high level of lactic acid explains in part the prolonged incapacity resulting from the ingestion of large amounts of alcohol. Two patients who were apparently well and not suffering from a hangover on the morning after their admission to the hospital were observed to have normal

lactic acid values within twenty-four hours of their admission.

THE OXIDATION OF ALCOHOL BY THE BRAIN

The following experiments present new evidence of the manner in which the body disposes of ingested alcohol. Some alcohol is excreted through the breath

Chart 2—Effect of alcohol ingestion on pH and lactic acid content of whole blood (experiment of Feb. 1, 1932)

and the urine, but most of it is oxidized. Since some of the chief effects of alcohol are on the central nervous system, it seemed important to determine whether the cerebrum could oxidize alcohol. The rapid shifts in the acid-base equilibrium make it difficult to evaluate the significance of the respiratory quotients of the brain of the living animal. Hence, respiratory quotients of the excised cortex of the rat were determined in the Warburg apparatus. The respiratory quotient of the cortex was determined because it may be an indicator of the foodstuffs oxidized. The respiratory quotient, it may be recalled, is the ratio between the volume of carbon dioxide produced during the oxidation of any substance and the volume of oxygen consumed in the

TABLE 9—Effect of Intraperitoneal Injection of 50 cc of 19 Per Cent Alcohol Per Kilogram of Rat on Respiratory Quotient

Respiratory Quotient of Excised Cortex of Rat

				0.51

process. The cerebral cortex is especially suitable for such a study, since it oxidizes carbohydrate, probably after conversion to lactic acid, as a source of energy. The respiratory quotient of carbohydrate and lactic acid is unity, in marked contrast to that of alcohol, which is 0.67. Thus, a clear differentiation may be made between the exclusive oxidation of lactic acid and of alcohol. The intermediate quotients observed in these experiments indicate that both alcohol and lactic acid are oxidized simultaneously (table 9). Thus, the cerebral cortex, like the body as a whole, may derive energy from the oxidation of alcohol. The presence of alcohol undoubtedly interferes with the normal functions of the central nervous system. The oxidation of alcohol by the body and particularly by the

cortex, an organ which usually oxidizes only lactic acid, may act as a protective device to rid the brain of a toxic substance

CONCLUSIONS

The ingestion of 10 cc of 19 per cent alcohol per kilogram of body weight by human subjects and of 50 cc per kilogram of body weight by dogs is followed by an acidosis. This acidosis is probably the result of two factors: a relative retention of carbon dioxide and the accumulation of lactic acid. The alkali reserve of the body is diminished because of this accumulation of lactic acid.

In patients suffering from the after-effects of over-indulgence in alcohol—the so-called hangover—there was an increased content of lactic acid in the arterial blood.

The brain, which usually derives its energy from the oxidation of carbohydrate, may nevertheless also oxidize alcohol.

THE FILAMENT-NONFILAMENT COUNT IN CHRONIC ARTHRITIS

AN AID IN THE DIFFERENTIATION OF RHEUMATOID
ARTHRITIS AND OSTEO-ARTHRITIS

OTTO STEINBROCKER, M.D.

AND

EDWARD F. HARTUNG, M.D.

NEW YORK

In our studies of the chronic rheumatic diseases we have resorted to various aids to facilitate the diagnosis and differentiation of chronic rheumatoid arthritis and osteo-arthritis. Because infection is considered the etiologic factor in some forms of these diseases, we have for some time sought diagnostic assistance from the study of the blood picture.

The total white count and the conventional differential count are not sufficiently enlightening in chronic arthritis.¹ In the study of acute infections, Schilling's

Fig 1—Cooke and Ponder's scheme illustrating Cooke's criterion: "If there is any band of nuclear material connecting the different parts of a nucleus that nucleus for the purposes of the count cannot be said to be divided."

modification² of the Arneht count has received widespread approval. In many chronic infections, however, particularly in the chronic rheumatic diseases, the procedure still has to demonstrate its value. Schilling³ states that "in rheumatoid conditions only slight changes in the hemogram are found." No extensive hemogram studies, outside of a few sporadic case reports,⁴ have

appeared in the literature of chronic arthritis until the recent study of Eaton.⁴ He reported 250 cases of chronic nontuberculous arthritis in which the Schilling hemogram showed a nuclear shift to the left, i.e., evidence of septic stimulation, in 90.4 per cent of the patients. He did not differentiate, however, in this series between rheumatoid arthritis and osteo-arthritis.

Without disparaging the value of the Schilling count for thorough, serial, diagnostic and prognostic blood studies, many workers have found it too cumbersome for routine use. This objection has led to a progressive simplification of Schilling's methods, notably by Pons and Krumbhaar⁵ here, and by Piney⁶ and Cooke and Ponder⁷ abroad. The most recent modification was the

Fig 2—Types of nonfilament neutrophils, 16; types of filament neutrophils, 7.

filament-nonfilament count advocated by Farley, St. Clair and Reisinger.⁸ The method involves a slight but fundamental change in Cooke and Ponder's classification of neutrophils. It appears to differ only in name from the classification described in 1927 by Roberts⁹ in his "lobulated and nonlobulated cell" count.

The filament-nonfilament count is a simple method of neutrophil study based on the changes advocated by the various authors mentioned. It is offered as a routine method of obtaining information from the neutrophilic leukocytes, unattended by the complexity of the Arneht and Schilling hemograms yet retaining their value as an index of toxic or infectious states.

The neutrophils are divided by this procedure, according to their age, into two classes. The first, or nonfilament group, consists of the young neutrophils in which the nucleus is unsegmented, or, if segmented, the nuclear parts are still joined by thick portions of nuclear material. The second, or filament, group consists of those neutrophils in which a fine filament of chromatin material connects two or more segments of the nucleus, i.e., the true polymorphonuclear cells. The distinction made by Farley and his associates is based on the dictum of Cooke and Ponder, "If there is any band of nuclear material except a fine filament of nuclear material connecting the different parts of a nucleus, that nucleus for the purposes of the count cannot be said to be divided."

Med.* 16: 306-310 (Dec.) 1930.

As a basis for any further studies, Farley, St Clair and Reisinger determined the normal filament-nonfilament count in 100 patients of their own series and recalculated the count in 90 normal persons previously reported by Cooke and Ponder. This work establishes the normal nonfilament count at 16 per cent or below and averaging from 8 to 9.8 per cent. Roberts, in a series of 117 normal persons, found the nonlobulated cells, which correspond to the nonfilament cells, constituting 25 per cent of the neutrophils. Using 65 per cent as the normal percentage of neutrophils in a differential count, he brought his figures to exactly 16 per cent in a count of 100 leukocytes of all types. Mullin and Large,¹⁰ in a series of acute infections, found the nonfilament count an effective diagnostic and prognostic aid. In seven chronic arthritis patients mentioned, they found a suggestive elevation of the nonfilament cells in those with infectious arthritis.

OBJECT

Our aim in this study was to determine whether, by routine filament-nonfilament counts, we could differentiate rheumatoid arthritis from osteo-arthritis. From November, 1931, to September, 1932, we took routine blood smears from all afebrile patients admitted to our arthritis clinic. From this group, in the order admitted, we selected fifty cases each of chronic rheumatoid arthritis and osteo-arthritis, diagnosed by other methods, for a comparison of their nonfilament counts. The accompanying table gives the results.

Nonfilament Counts

Case	Rheumatoid Arthritis	Osteo-Arthritis	Case	Rheumatoid Arthritis	Osteo-Arthritis
1	33	12	26	32	22
2	27	27	27	26	10

23	33	20	48	37	14
24	47	14	49	29	14
25	33	12	50	33	32

METHODS

The method of blood examination followed the criterion of Cooke and Ponder. McNeill's polychrome stain was used but the ordinary Wright stain was also found satisfactory. Thin uniform smears on scrupulously clean slides proved reliable. A total differential count of 100 cells was done on each slide. Most of the counts were performed by two different workers, and each of these nonfilament counts, when checked, showed a variation of only 1 to 3 per cent. The blood smears were taken at the same time of day. Repeated counts were done in a majority of the cases but are not

considered a part of this study. Total leukocyte counts were not done, because we did not think they would add sufficient information to warrant the additional labor. We found that any one familiar with blood cytology could acquire the necessary technic with a little practice. Borderline cells, difficult to classify, occur rarely enough to be negligible.

RESULTS

The nonfilament count was found above normal in 100 per cent of the chronic rheumatoid patients. In twenty-six patients, or 52 per cent of the osteo-arthritic patients, the count was normal. The average nonfilament count in the rheumatoid patients was 31.5 per cent, while in osteo-arthritic patients with an abnormal count the nonfilament cells averaged 22.3 per cent.

COMMENT

Whether osteo-arthritis and rheumatoid arthritis are different disease entities, distinguished by the presence or absence of an infectious process, is a problem that we will not consider here. Our purpose in this study is to report the observations in a selected group of patients of each type. If chronic infection is a factor, one may reasonably expect some blood reaction in response to the mild but persistent "stimulus exerted by the pathological process."¹¹ The uniform elevation in the rheumatoid group points to the presence of an infectious agent in this disease.

It is interesting to speculate on the explanation of the elevated count in approximately half of the patients with osteo-arthritis. The question arises at this point whether our present standards of differentiating this condition are adequate. Clinical study has led us to believe that a good proportion of this group represents the so-called mixed type of arthritis, osteo-arthritis with an associated rheumatoid disease. If this is true, it accounts for many of the elevated nonfilament counts in the osteo-arthritic group.

The remainder of the abnormal counts in the osteo-arthritic group may be due to associated focal infection. Our observation in a variety of cases has indicated that the filament-nonfilament count is an index to otherwise unrevealed sepsis. We have several times been led by a persistently high nonfilament count to reexamine a patient. In each instance an active focus was discovered which had previously been overlooked or unsuspected. We are now conducting further studies along these lines.

CONCLUSIONS

1 The filament-nonfilament count is a useful routine diagnostic aid in chronic arthritis.

2 Filament-nonfilament counts in fifty patients with rheumatoid or chronic infectious arthritis were abnormally elevated in 100 per cent of the patients.

3 The filament-nonfilament count was normal in twenty-six patients, or 52 per cent, of a group of osteo-arthritic patients, while in the rest of this group the count was elevated.

4 The average nonfilament count was much higher (31.5 per cent) in patients with rheumatoid arthritis than in osteo-arthritic patients with an abnormal count (22.3 per cent).

5 The filament-nonfilament count is helpful in differentiating rheumatoid arthritis from osteo-arthritis only when within normal limits. A normal count indicates that chronic rheumatoid infection is not present.

OBLITERATING SYPHILITIC ARTERITIS

LYLE MOTLEY, M D
AND
ROBERT MOORE, M D
MEMPHIS, TENN

Obliteration of the larger arterial trunks when due to atheroma, arteriosclerosis or Buerger's disease is a fairly familiar clinical condition. Syphilitic obliteration of the larger vessels, however, would appear from the literature to be a fairly uncommon condition and is not seen often in clinical practice.

The case here reported initiated a search of the literature on the subject and while numerous reports were found of obliteration of the larger vessels as a result of arteriosclerosis and atheroma, the percentage of cases in which the obliteration was due to syphilis would suggest that our case represents a fairly rare condition, or at least one that escapes clinical notice. Encroachment on, and at times complete obliteration of, the orifices of coronaries are frequently seen at postmortem as the result of syphilis of the aorta. However, the larger vessels which leave the aorta are apparently but rarely involved by the syphilitic process in the aortic wall to the extent of encroaching on their lumen. Gurd and Wade¹ discussed syphilitic intimal arteritis from simple proliferation of the intima, but no occlusion of large trunks is reported by them. Darling and Clark² collected six cases of occlusion of large vessels, including the carotid, innominate, subclavian, renal and mesenteric arteries, and their conclusions were that 37 per cent of syphilitic cadavers at autopsy show some occlusive lesions. Other authors report oblitative lesions of the larger vessels, the majority of them being due to arteriosclerotic and atheromatous lesions. The only case in the literature which seems at all identical with the one reported here was one reported by Preisdorfer³ in 1878, in which the obliteration of the vessels was identical in character and location with ours, but which was complicated by aneurysm, which was absent in our case.

REPORT OF CASE

A white woman, aged 29, was admitted to the Baptist Hospital with the complaint of marked dyspnea, smothering spells, edema of the feet and legs, and lately abdominal swelling. The onset of symptoms was insidious, and they became pronounced about four weeks before admission. The past history was essentially negative, except for attacks of tonsillitis in childhood and early youth and recurring spells of fairly severe acute arthritis, chiefly in the knee and wrist joints, over a period of two or three years, terminating about seven years previously. Physical examination showed essentially a patient who was markedly dyspneic and was obviously in advanced heart failure. Edema of the extremities and dependent portions was marked and much ascites was present with free fluid in the right side of the chest. Except for the observations referable to the heart and peripheral circulation, physical examination showed nothing of particular interest. Examination

of the heart showed classic signs of aortic insufficiency with the typical diastolic murmur being present. Except for the following unusual features, the patient presented a typical example of the usual case of aortic insufficiency encountered in routine hospital practice. There was marked pulsation of the vessels of the neck on the right side, with a Corrigan pulse at the right wrist, and in the right arm the blood pressure was 170 systolic, 0 diastolic. The left side of the neck showed no arterial pulsation, the pulse was well sustained at the left wrist, there was no capillary pulsation in the left upper extremity, and the blood pressure was 95 systolic, 70 diastolic in the left arm. Capillary pulsation was present in both lower extremities when elevated above the level of the heart, and Duroziez's sign was positive in both femoral arteries. A teleroentgenogram of the chest showed no evidences of aneurysm, and the appearance of the heart shadow was that which is usual in advanced heart failure with aortic insufficiency. The electrocardiogram was in keeping with the clinical observations and showed nothing remarkable. A blood Wassermann test obtained before death was reported positive after the autopsy.

The patient died about twenty-four hours after admission to the hospital and the autopsy showed nothing of especial interest except the changes in the aorta, which were typical of syphilitic aortitis with aortic valve insufficiency. Of special interest, however, was the almost complete obliteration of the orifices of the subclavian and left carotid arteries as a result of the proliferative syphilitic process in the aortic wall. The opening into these vessels would not much more than accommodate the shaft of a small pin, which easily explained the blood pressure in the left arm in contrast to the classic pressure of aortic insufficiency in the right arm. The small orifices of the two larger vessels exerted a valvelike action and allowed blood to flow into these vessels only slowly and, when they were filled, sustained pulse and blood pressure by preventing a sudden reflux back into the lumen of the aorta. Sections of tissue taken from the aorta around the orifices of these vessels showed microscopically typical syphilitic mesaortitis and proliferation of the intima, which had encroached on the mouths of the vessels. Special staining methods showed enormous numbers of *Spirochaeta pallida* in the aortic wall.

COMMENT

The age and sex of the patient and the unusual clinical observations, particularly the discrepancy in blood pressure between the two arms, would appear to make this case of sufficient interest to warrant reporting. This would seem to be still more true, since nothing can be found in the literature regarding obliteration of isolated large vessels from any cause since 1925.

Such isolated oblitative lesions should probably be considered clinically and sought for more diligently at autopsy than has apparently been the custom in the past, since they can easily explain unusual and at times vague signs and symptoms for which no basis can be found clinically. Oblitative lesions of the carotid from atheroma and thrombosis resulting in cerebral and other neurologic manifestations are reported.⁴ It is conceivable that similar processes, whether from syphilitic lesions or other conditions, could easily cause vague visceral disturbances, such as unexplained abdominal symptoms. Syphilitic involvement of the pulmonary vessels in the form of Ayerza's disease is being recognized clinically and reported with greater frequency. It is entirely possible that instances of oblitative vascular lesions causing other clinical manifestations will be reported with greater frequency as such conditions are more frequently brought to our notice and autopsies more regularly and more thoroughly done.

THE USE OF CORTIN IN A CASE OF ACUTE HYPOSUPRARENALISM OCCURRING AS A SEQUELA OF ACUTE STREPTOCOCCIC SORE THROAT

J. HOLDEN ROBBINS, M.D., MADISON, WIS.

History—A woman, aged 25, on the afternoon of April 7, began to have symptoms of general malaise, aching pains throughout the body, headache and slightly sore throat. There was no cough or expectoration, nor were there symptoms referable to the central nervous, cardiovascular, gastro-intestinal or genito-urinary systems. The patient had made a complete recovery three days previously from an attack of acute appendicitis, without operation.

Examination—Physical examination revealed the following pertinent points. The patient was well developed and well nourished. The temperature was 99.6 F, pulse 90, respiration rate 20. The mucous membrane of the nasal cavity was inflamed and congested, the tongue coated, the pharynx inflamed. The tonsils were inflamed and enlarged. There was no rigidity and no abnormal pulsations in the neck, there were a few enlarged cervical lymph nodes. The chest was well developed, the expansion was good and equal, the resonance was normal throughout, the breath sounds were normal, there were no rales. The heart was of normal size and position, with no thrills or murmurs. The abdomen was soft, with no tenderness or rigidity and no masses. The neuromuscular reflexes were normal, there were no paralyses. Symptomatic treatment such as a gargle and salicylates was advised.

At 10 p.m. the patient was seen again. At this time the temperature was 104.6, pulse 120, respiration rate 24. She was extremely toxic. There was inflammation and edema of the pharynx with a beginning membrane formation over the left tonsil. The heart, lungs and abdomen showed no pathologic condition at examination. The diagnosis was quite obviously acute streptococcic sore throat. A smear and culture taken from the nose and throat at this time was negative for diphtheria but showed a heavy growth of streptococci. The patient was put under the care of a competent trained nurse.

Course—April 8, the patient was extremely toxic, with a temperature of 104, pulse of 124 and respiration rate of 30. There was an extensive membrane on the left tonsil with deep friable ulcers in the surface of the tonsil. The entire pharynx was edematous and inflamed. The nasal mucous membrane was inflamed and congested. The heart and lungs showed no pathologic changes. The blood pressure was 114 systolic, 76 diastolic. The blood count revealed hemoglobin 70 per cent, red blood cells 3,800,000, white blood cells 23,000, with 97 per cent of polymorphonuclear leukocytes. The urine showed a trace of albumin, there were no casts, pus or red blood cells.

April 10, the temperature still remained above 104, the pulse was from 110 to 120, the respiration rate from 26 to 30. The patient remained extremely toxic. The heart and lungs presented no pathologic changes. The blood pressure was 110 systolic, 70 diastolic. The pharynx was less edematous and the patient was able to swallow with more comfort. An erythematous rash much like that of scarlet fever had developed but there were petechial hemorrhages scattered over the surface of the body, especially where there were folds or creases in the skin. Movement of almost any joint in the body caused excruciating pain. Examination of the joints revealed tenderness but no swelling or inflammation.

April 11, the temperature was between 101.6 and 103 and the pulse from 100 to 110. The blood pressure was 114 systolic, 78 diastolic. The pharynx both objectively and subjectively was very much improved. The joint pains and rash remained about the same. The urine was loaded with albumin, pus and red blood cells and it contained many granular casts. Chemical examination of the blood revealed nonprotein nitrogen 75 mg. per hundred cubic centimeters of blood, white blood cell 32,000 with 68 per cent of polymorphonuclear leukocytes.

April 12, the patient's temperature registered between 101 and 102, the pulse was from 90 to 100. The pharynx and tonsils were greatly improved. The rash was fading and the skin peeling. The pain on movement of the joints was much improved, with the exception of the right shoulder. The urine was still loaded with albumin, pus, red blood cells and granular casts. There was no edema or shortness of breath. However, the patient complained of being extremely weak, she was nauseated and had aching pains in the loins. The blood pressure was being watched closely because of the apparent kidney involvement. The morning reading was 65 systolic, 45 diastolic.

April 13, the patient was irrational and showed signs of mental depression. She was continually nauseated, and the vomiting was profuse. There was extreme exhaustion, she was unable to lift her arm off of the bed, or her head from the pillow. There were severe aching pains in the lower part of the back and the hips. There was no desire for food of any kind. The temperature ranged between 98.6 and 99.8. The joint pains had entirely disappeared except for the right shoulder. The tonsils and pharynx were normal. The urine showed a trace of albumin, with an occasional hyaline cast, no pus, no red blood cells and no granular casts. The blood pressure was 55 systolic, 35 diastolic. The Muirhead treatment for suprarenal insufficiency was started. The blood pressure could be brought to 80 systolic immediately after the hypodermic injection of 15 mm of 1,000 epinephrine hydrochloride.

April 14, the blood pressure readings were between 60 and 80 systolic. There was marked anorexia and extreme nausea and vomiting. The patient was becoming very much dehydrated. There was marked exhaustion and severe mental depression. There was severe pain in the loins. Small amounts of highly concentrated urine were obtained by catheter. Urinalysis revealed specific gravity, 1.042, no albumin, no pus, no red blood cells and no casts. I communicated with Dr. Hartman of the University of Buffalo Medical School in an effort to obtain a supply of cortin for clinical use.

April 15, the patient's condition was very grave, and little hope was held for recovery from the moribund state which she had reached. The blood pressure could not be brought above 60 systolic, in spite of seven ampules of 1,000 epinephrine hydrochloride given hypodermically in addition to the ordinary Muirhead treatment.

April 16, the condition was practically the same as the day before. The blood pressure was 60 systolic, 40 diastolic. The patient could be roused only with difficulty from her lethargic condition. At 10 a.m., 70 cc. of cortin arrived from Dr. Hartman's laboratory. The patient was given 5 cc. subcutaneously every six hours for the first twenty-four hours. Following the second dose of cortin the patient's blood pressure had risen to 110 systolic, 70 diastolic. Her mental condition had changed entirely in the course of a few hours. She was hopeful instead of depressed. Nausea had entirely disappeared and she took large amounts of fluids by mouth. She mentioned hunger for the first time in several days.

April 17, the patient's general condition was improving rapidly. The temperature was 98.6, pulse 84, systolic blood pressure from 100 to 114. There was no nausea or vomiting, and the appetite was good. Pain in the lower part of the back had entirely disappeared. Cortin 5 cc., was given twice a day.

April 18, the patient's condition was so good that she wanted to get out of bed. The blood pressure was from 110 to 120 systolic and from 70 to 80 diastolic.

April 22, subjectively and objectively the patient was very much improved. All local signs of infection had disappeared. Nonprotein nitrogen was 32 mg. per hundred cubic centimeters of blood. The urine showed no albumin, pus, red blood cells or casts. The last dose of cortin was administered. The patient's condition was sufficiently improved to enable her to travel about 50 miles to her home, by train. Before the development of this illness the patient weighed about 115 pounds (52 Kg.). Her estimated weight at the time she left for her home was approximately 90 pounds (41 Kg.).

May 4, the patient found that she tired easily but that she was gaining strength slowly. The blood pressure was 114 systolic, 70 diastolic. The blood count was hemoglobin 85 per cent, white blood cells 7,200 with 65 per cent of polymorphonuclear. The urine was negative for albumin, pus, red blood cells and cast. Her weight was 90 pounds (43.5 Kg.).

June 6, the patient was still weak but had gained sufficient strength to do part time work. Her weight was 104 pounds (47 Kg). The blood pressure was 118 systolic, 76 diastolic. The patient was losing the hair from her scalp, and she was also losing her finger and toe nails. The urine was negative for albumin, pus, red blood cells and casts. Hemoglobin was 90 per cent, white blood cells 7,500.

June 15, the patient's general condition was very good. She was doing full time work and able to play tennis and golf. Her hair and finger nails were coming in normally. Her weight was 110 pounds (50 Kg). The blood pressure was 118 systolic, 78 diastolic.

July 25, the patient's condition was very good. She weighed 112 pounds (51 Kg). The blood pressure was 122 systolic, 84 diastolic.

Summary—A case of acute streptococcic sore throat had the following complications in the order of their occurrence: first, a severe toxic joint manifestation characterized by severe pain on movement with no signs of inflammation or swelling; second, a severe scarlatiniform toxic rash with many petechial hemorrhages; third, a marked toxic nephrosis characterized by albumin, pus, red blood cells and granular casts in the urine, with a retention of nonprotein nitrogen of 75 mg per hundred cubic centimeters of blood; fourth, definite damage to the suprarenal cortex, as evidenced by the low blood pressure, anorexia, nausea and vomiting, loss of weight of 20 pounds (9 Kg), characteristic pain in the loins, mental depression, definite temporary mental changes, extreme weakness and exhaustion.

COMMENT

"Apart from the lesions of Addison's disease and neoplasms, the adrenals are not often the seat of disease of clinical interest." This quotation, from Steven's Practice of Medicine, portrays the general concept of the medical profession in relation to the involvement of the suprarenal glands as a result of acute infectious diseases. There are three pairs of suprarenal arteries: a superior from the inferior phrenic, a middle from the aorta, and an inferior from the renal. Thus, this small gland weighing about 7 Gm, has three well developed arteries and consequently a very rich blood supply. The kidneys are frequently involved, by way of the blood stream, secondary to acute infectious diseases or foci of infection, both seriously, in the form of acute nephritis which frequently eventuates in chronic nephritis, and less seriously, in the form of acute nephroses. One of the three blood vessels of the suprarenal gland is a branch of the renal artery, so that any toxins or bacteria which reach the kidney and cause damage there have an equal opportunity to pass through the suprarenal glands. There is no basic reason for believing that the tissue of the suprarenal glands is more resistant to infections and toxemias than any other gland in the body. Degenerative changes such as cloudy swelling and fatty degeneration do occur in the suprarenal tissue. These considerations make me believe that many of the symptoms, such as weakness, exhaustion, pain in the back, gastro-intestinal disturbances, slow convalescence and loss of weight, which often occur in association with acute infectious diseases, may be due in part to unrecognized suprarenal insufficiencies.

The use of cortical extract has not been satisfactory in the treatment of typical Addison's disease, when there is an extensive and permanent damage to the suprarenal glands consequent on tuberculosis or malignant disease. This is, in a large measure, due to the fact that the therapy is merely replacement in nature, since the pathologic changes involving the gland are usually permanent and progressive.

The results of treatment with cortical extract of the case reported and those typical cases of Addison's disease differed in only two respects. First the blood pressure in the case reported returned to normal limits and has been maintained there; second, the patient has required no treatment for several months and has steadily improved. For these reasons and because the kidney complications cleared up so promptly, I feel that the damage to the suprarenal glands was toxic and temporary, and that no permanent pathologic condition has resulted.

What is chronic hyposuprarenalism? I have come to the conclusion that there is a large group of patients who are suffering from chronic hyposuprarenalism. They complain of

a characteristic group of symptoms such as lowered blood pressure, lack of energy and ambition, rapid fatigue on exertion, vague gastro-intestinal symptoms with no pathologic background, and mental depression. The usual diagnosis in these cases is neurocirculatory asthenia. I have been treating these patients with whole gland suprarenal substance with fairly encouraging results.

CONCLUSIONS

1 A case of acute hyposuprarenalism occurred as a complication of acute streptococcic sore throat.

2 The results of treatment with cortin in this case were very satisfactory. (The cortin was obtained from Dr Hartman's laboratory in Buffalo.)

3 It is suggested that acute hyposuprarenalism may occur more often than is usually believed.

4 If chronic hyposuprarenalism is a definite entity, cortical extract may prove of extreme value in combating its distressing symptoms.

607 First Central Building

A SECOND CASE OF GASTROINTESTINAL ALLERGY DUE TO INSULIN

JOHN R. WILLIAMS, M.D., ROCHESTER, N. Y.

In 1930 I¹ reported a case of allergy due to insulin affecting the gastro-intestinal tract and producing severe symptoms. Briefly, a boy of 12 years, having had diabetes since the age of 7, began to have severe attacks of abdominal pain, nausea and vomiting. These were so severe in each instance as to precipitate coma. After a short stay in the hospital, with treatment consisting of free intravenous infusions of salt solution and dextrose, the child would return home, to repeat the experience when his usual diet and insulin therapy were resumed. Several such attacks occurred. In the last one, while the patient was moribund, the possibility of an insulin allergic reaction was considered. A change from an insulin of pork to one of beef origin was made. The patient obtained immediate and permanent relief and has been well since, after an interval of three years. The case was studied carefully from both allergic and clinical points of view, and the conclusions were correct beyond question.

Allen² of the Mayo Clinic reviewed the conclusion that I arrived at in this case and suggested that the phenomenon might be due to acidosis. In reply it may be said that there is no similarity between the picture presented by this child and the pain that supervenes in diabetes. It is well known that in the profound acidosis which precedes coma, for a few minutes, and for rarely more than an hour, a severe pain in the epigastric region may occur. As the coma develops, the pain disappears. This phenomenon is often mistaken for appendicitis, gallbladder disease or pneumonia, and more than one diabetic patient has been operated on because of it. Its cause has been ascribed to irritation of the phrenic nerve. Be that as it may, the picture of the profound gastro-intestinal disturbance extending over a period of several months as presented by this boy is an entirely different phenomenon.

I have seen another case quite similar in character. The proof was established by positive tests. The patient, a married woman, aged 52, gave a history of diabetes extending over a period of six years, during which she had taken insulin constantly.

In September, 1931, she began to have a gastro-intestinal disturbance, which was characterized by cramps followed by frequent bowel movements. She would have four or five stools during the day, with none during the night. In December, 1931, she noticed a slight edema of the upper eyelid. Repeated physical examinations of the abdomen revealed no evidence of organic lesion. The phenomenon occurred almost daily for the succeeding nine months and did not yield to medication or dietary regulation. In January, 1932, a roentgen study was made by Dr. John A. Bennett of Elmira, N. Y. This examination revealed no evidence of disease in the chest. There was a

From the Highland Hospital.
1 Williams, J. R. Allergic Insulin Reactions, J. A. M. A. 94:1112 (April 12) 1930.
2 Allen, F. M. and Scherer, L. R. Insulin Allergy, Endocrinology 16:417 (July Aug.) 1932.

marked hyperperistalsis with rapid emptying of the entire gastro-intestinal tract, but no evidence of ulcer or new growth. The gastro-intestinal symptoms becoming more severe, surgical advice was sought and operative intervention was seriously contemplated.

Up to this time the patient had been using insulin of pork origin, but through an inadvertence was given an insulin derived from the beef. With this change, the gastro-intestinal symptoms immediately disappeared. Since that date, the patient has remained well. Skin tests for insulin sensitivity were made with pork and beef insulin. A marked reaction was elicited from the pork insulin, which persisted for more than twenty-four hours. The evidence of the test from the beef insulin completely disappeared in twenty minutes. The diagnosis was further confirmed by the fact that the intradermal test also caused a typical gastro-intestinal attack. Several days later a therapeutic dose of pork insulin produced the characteristic abdominal upset. Since the use of beef insulin, she has been entirely free from gastro-intestinal symptoms.

This second case is reported because, among the thousands of individuals who are now taking insulin hypodermically, cases of allergic reactions undoubtedly occur, which are now being overlooked. Since gastro-intestinal allergic reactions are so likely to be confused with the common organic lesions of the abdominal tract, such as appendicitis and gallbladder disease, physicians undertaking the care of diabetic patients should be on the lookout for this phenomenon and should rule it out before attempting surgery.

388 Monroe Avenue

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY OF THE AMERICAN MEDICAL ASSOCIATION HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS
H. A. CARTER, Secretary

AIRGARD VENTILATOR NOT ACCEPTABLE

The Aircard Ventilator and Filter (Model 30), designed to supply a variable quantity of filtered air to the average sized office or room, is manufactured by the American Air Filter Co., Inc., Louisville, Ky.

The Aircard is contained in a metal cabinet 24 inches wide, 9½ inches deep and 9 inches in height, and it can be installed easily in any window of the vertical sash type. All necessary parts and appurtenances for installation in this type of window are supplied by the manufacturer with each machine. In special sashes, such as factory type or French windows, special installation is necessary.

A relatively quiet and efficient electric motor is directly connected to a Sirocco type blower fan. Outside air is drawn in through a screened vent in the lower back portion of the machine and is conducted upward through a duct to the top of the apparatus where the cellulose filter is placed. After passing through the filter sheets the air is forced by the fan into a discharge duct. From the discharge duct the air passes into two circular openings which are protected by louvers that may be rotated through an angle of 360 degrees making it possible to direct the current of the incoming filtered air in various directions.

The Aircard is equipped with a recirculating feature. A damper closes the intake air duct. If this damper is shut and a series of apertures at the top of the device opened by a sliding shutter air is drawn through the holes directly from the room. Then it is filtered and re-discharged back into the room.

In extremely hot or cold weather it may be desirable to filter and recirculate the air in the room.

The speed of the motor designed for this unit can be regulated by a variable resistance controlled by a knob on the outside of the machine. Current consumption is about 40 watts per hour. At the Chicago rate the Aircard will run approximately ten hours for four cents.

By the use of the variable speed control the quantity of filtered air may be varied from approximately 60 cubic feet per minute minimum to over 160 cubic feet per minute maximum (with one filter sheet).

The manufacturer claims that this filtering medium is 97 per cent efficient when only one filter sheet is used. The filtering efficiency of the machine is increased by using two or three sheets at one time, but the air capacity is reduced. Filter sheets are changed easily by simply raising the cover of the machine, lifting out the retaining grill, and removing the old sheet. A fresh filter sheet is laid in, care being taken that all edges are tightly held down by the retaining grill, as the filter sheet is apt to be dislodged.

Standard equipment includes one dozen filter sheets. Renewal filters may be purchased at the price of \$1.50 per carton of twenty-four oil charged sheets.

When the Aircard is used in the treatment of hay fever and asthma, a few precautions are necessary. The company recommends that two or three filter sheets be used at a time. However, it is to be remembered that the volume of air flow per minute is reduced when more filter sheets are added.

In a Council test covering a period of seven days, the pollen filtering efficiency of the Aircard was tested. Each day of twenty-four hours, two petroleum coated slides were exposed about one inch from the louvers at an angle slightly less of being perpendicular to the blast of incoming air. The investigation proved that very little ragweed pollen passed through the filter (three sheets). Slides for each day were submitted to two specialists in the field, who counted the pollen granules.

The volume of air was measured by means of a Tycos anemometer. The committee investigating the device is aware that some authorities believe a Pitot tube is a more accurate instrument than the anemometer to use for this determination. If a Pitot tube had been employed, it is probable that the recorded volume of air displaced would be slightly higher. Nevertheless, the committee believes that the observations herein recorded are relatively accurate.

If the Aircard is installed in a small office or bedroom, the Council believes that the unit will supply a sufficient volume of filtered air for a person suffering from hay fever. On hot sultry days, however, in order to secure comfort in the closed room, a fan may be necessary to keep the filtered air in constant circulation. All clinical evidence coming to the attention of the Council indicates conclusively that patients are relieved only when they remain in a filtered atmosphere. Evidence that a hay fever patient will obtain relief for the entire day by merely remaining in a filtered air room for eight hours more or less is lacking.

The Council reports the Aircard unacceptable because of the objectionable character of the advertising matter. The manufacturer being told that the pamphlet 'Clean Air and Quiet for the City Dweller' was unacceptable to the Council, informed

Results of Tests

Date	8/27	8/28	8/29	8/30	8/31	9/1	9/2
Aircard (average of two observers)	4	3	11	5	16	3	2
Outdoor air	552	271	389	461	323	77	183
Humidity	84		86	82	82	65	73
Wind direction	N W		S W	S W	S	N E	N E
Temperature		66	85	85	82	70	72
Air displacement (corrected for wind velocity)	1st day—3 new filter sheets—98 cu. ft. per min. 2d day—same 3 filter sheets—96 cu. ft. per min. With one filter sheet only—159 cu. ft. per min.						
Power	40 watts						

the Council that the use of the objectionable pamphlet had been discontinued. This decision was reiterated in the firm's letter of a later date.

The aforementioned objectionable pamphlet was replaced by a bulletin entitled 'Filtered Air in the Prophylaxis and Treatment of Allergic Diseases' and, in fairness to the manufacturer it must be said that the character of this advertising matter has been greatly improved. However, the Council found certain claims in the reading matter still objectionable and misleading for example suggesting unfiltered air as prolific causes of common colds and other ills, and interludes with digestion and prolific causes of deafness. The manufacturer should support these claims by conclusive scientific evidence. In the opinion of the Council, promotional literature containing claims of this kind constitutes an appeal to the public with arguments that are unscientific and may harmfully enhance a feeling of false security on the part of the public.

The Council on Physical Therapy believes that the Airdard will supply enough filtered air for a small office or bedroom occupied by two or three people and will serve as an adjunct in the relief of symptoms of hay fever. However, the Council declines to accept the apparatus for inclusion in its list of accepted devices because the firm makes claims in advertising matter not substantiated by acceptable scientific evidence.

SIMPLEX DIATHERMY MACHINE NOT ACCEPTABLE

The Simplex Diathermy Machine is manufactured by the Simplex Diathermy Company, 333 West Fifty-Second Street, New York City. It is a small diathermy machine that is advertised principally by radio and sold directly to the public. The instruction for its use is given largely by lay salesmen. The quarters now occupied by the Simplex Diathermy Company formerly housed the Therapeutic Institute, 333 West Fifty-Second Street, New York.

The Simplex Diathermy Machine was examined in the home of a patient who bought it from the Simplex Diathermy Company. It comes in a handy carrying case, size about 12 by 18 by 6 inches. The cord can be directly plugged into the alternating light circuit, but if the current supply is direct current, a rotary converter is furnished by the company at an additional expense. It weighs about twenty pounds.

A snap switch on the panel connects the machine with the main line. Regulation for modifying the strength of the current drawn from the line is missing. A two-section, four point spark gap, with a regulation cooling device is mounted on the panel of the machine. Each section of the spark gap can be separately regulated. There is no covering protection over the spark gap. Varying the opening of the two sections serves as the only regulation of the current intensity. A milliamper meter is not furnished with the machine. Presumably the person is told by the salesman that a meter is not necessary because he gets enough current as long as he feels a comfortable heat under the plate.

Two outlets on the panel are marked "patient's circuit". Conducting cords and the usual blocked tin electrodes are furnished, and patients are instructed by the salesmen where and how to apply the electrodes, according to the sick person's complaint.

The open and exposed spark gap makes it a dangerous instrument in a layman's hands, and the electrical capacity of the machine excludes any effective heating except when applied over small portions of the body.

With the current turned on and a cylindric electrode in each hand, a simple test showed that the maximum capacity of the machine with the spark gap open wide was 300 milliamperes.

The sick person heard the advertisement over the radio. He called the company, and a lay salesman was sent, who sold him the machine and showed him how to use it. Apparently this patient was suffering from myocardial degeneration, with chronic bronchitis, as shown by edema in both legs. He coughed frequently. The sick man said that the salesman told him that he could treat his lungs by putting one plate on his chest and the other one under both feet.

In the opinion of the Council, the selling methods of the company unquestionably constitute a direct violation of the practice of medicine. The salesman calls on any person who telephones or writes and assures him that the machine will be good for what ails him, and if the sale is made, the salesman proceeds to instruct the buyer how to use it.

If the diathermy machine had sufficient electrical energy to be useful in some of the conditions mentioned in the booklet "Diathermy Theory Treatment and Science," it would be an extremely dangerous appliance to place in the hands of a layman. It would be ridiculous to consider this unit effective for supplying surgical cutting currents.

In the opinion of the Council on Physical Therapy, the Simplex Diathermy Company is practicing methods that are detrimental to rational therapeutics. Promotional radio advertising by those unqualified to practice medicine constitutes an appeal to the public with arguments which are unscientific and may harmfully enhance a feeling of false security on the part of the public.

The Council declares the Simplex Diathermy Machine inadmissible to its list of accepted devices.

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING RELATIVELY RECENT DECISIONS FOR THE INFORMATION OF BOTH THE PROFESSION AND THE MANUFACTURERS

PAUL NICHOLAS LEECH, Secretary

RECENT REVISIONS OR ELABORATIONS OF THE COUNCIL'S RULES OF INTEREST TO MANUFACTURERS AND THE MEDICAL PROFESSION

1 Use of Numerals or Letters in the Names of Medicinal Products

In general, the Council holds that trade names of drugs, when permissible, must be so framed as to indicate the potent element or constituent. There has been an increasing tendency to incorporate numbers in the names of medicinals in advertising to physicians. Such emphasis on numbers or letters undoubtedly tends to displace names and thus lead to confusion. It is the Council's desire to discourage the use of numbers, so far as prescribing is concerned, and to restrict the use of numbers to catalogue identification, in ordering from wholesalers and in storage on shelf. The Council held it advantageous, therefore, to establish a rule against the use of numerals or letters in connection with the names of accepted articles on labels, in New and Nonofficial Remedies, and in advertising, unless the number is clearly separated from the name and subordinated to the latter by type and, if feasible, by position. In accordance with this decision the Council voted to amend the comments to its rule concerning trade names by addition to the following statement:

Since the use of numerals or alphabetical designations in connection with drug names tends to take the emphasis away from the name and to displace the name, thus leading to confusion, the Council will not recognize the name of a drug in which the numeral or letter is an integral part of the name, except in special cases where the use of a numeral or letter seems desirable because further improvement of the product is anticipated in which case the Council may grant a special exemption from the rule. Under this rule the use of numerals or letters in connection with the name of a product will not be permitted on labels or in advertising unless the numeral or letter is clearly separated from and subordinated to the name by type and if feasible by position. This rule shall not apply to price lists and catalogues.

The statement as amended will appear in N N R, 1933, page 19 ("Proprietary [Trade] Names When Permitted")

2 Labeling of Ampules to Indicate Excess Content

In a report to the Council on a product marketed in ampules, it was brought out that whereas the ampule was labeled "total content of each ampule 2 cc" it was found that an average of 2.1 cc, could be withdrawn from the ampules. It was explained that it has become customary among manufacturers of pharmaceuticals to place in an ampule a slight excess over the amount which it is desired to withdraw.

This question has had extensive consideration by the Combined Contact Committee of the American Drug Manufacturers' Association and the American Pharmaceutical Manufacturers' Association in collaboration with the Food and Drug Administration of the U S Department of Agriculture and a special committee representing the American Medical Association.

The ninth report of this Combined Contact Committee issued by the Food and Drug Administration in January, 1932 summarizes the work done and the conclusions reached. In commenting to the Council on this report, the Council's Committee on Rules and Procedure pointed out that the term "— cc size" was agreed on by this Contact Committee as an acceptable designation of the contents of ampules, that the significance of the term "— cc size" was understood to be that the ampule contained a sufficient excess of medicament to permit the withdrawal and administration of the quantity indicated by the size denomination, that the solicitor of the Department of Agriculture had given the opinion that the spirit of the federal Food and Drugs Act would not be violated if ampules so designated

as to volume of contents contained in addition to the volume indicated only sufficient excess to insure withdrawal and administration of the amount indicated by the size, and that the Food and Drug Administration would be guided by the solicitor's opinion

The Contact Committee's report refers to "extensive experimental data designed to determine the volumes of different types of liquids which any specified ampule should contain to permit the physician to withdraw and administer to his patient the indicated dose"

Under the circumstances it seemed advisable that the Council should abide by the conclusions reached by the Combined Contact Committee and frame its ruling in accordance therewith

In accordance with the recommendation of its Committee on Rules and Procedure, the Council voted to amend the paragraph on "Statement of Composition," New and Nonofficial Remedies, 1932, page 14, by the addition of the following

In the case of solutions marketed in the form of ampules the term — cc size will be accepted as a proper indication of the volume of contents the significance of that term being understood to be that the ampule contains a sufficient excess of medicament to permit the withdrawal and administration of the dosage indicated by the size denomination. Individual ampules or unit packages thereof must bear a statement explaining the significance of the term size as it applies in a given instance. For example if ampules are labeled 2 cc size a satisfactory statement will be Each ampule contains a sufficient amount to permit withdrawal and administration of 2 cc.

3 Statement of Potency of Liver Extracts

The manufacturer of an accepted liver preparation wrote to the Council objecting to the statements found in the New and Nonofficial Remedies descriptions, and in the advertising and labels of such products, to the effect that a certain amount of the extract represents, or is equivalent to, a certain amount of fresh liver. The manufacturer stated that his objection was based on the ground that such statements imply a 100 per cent extraction of the active principle from the liver. In considering this matter, the Council agreed that it is necessary to avoid any implication of 100 per cent extraction. In regard to liver extracts and, indeed, with regard to any unknown chemical substance or substances shown to have therapeutic properties, and in consideration of the almost certainly variable degrees of efficiency in extraction procedures, to say nothing of the variability in response on the part of individual patients reasonable assurance of a reliable product for the physician's use is all that can be expected until more exact methods of assay are available. The Council held that such a statement affirming that a given quantity of extract represents or is equivalent to the antianemic potency of a given quantity of liver, does not imply a 100 per cent extraction but an equivalence checked at least originally by therapeutic assay. The Council therefore ruled that manufacturers of liver extracts shall be required to limit statements concerning the potency of the representative fraction marketed to the affirmation that a given quantity of extract represents or is equivalent to the antianemic potency of a given quantity of fresh liver

4 Use of Chemical or Pharmaceutic Name

One paragraph of the comments to Rule 8 (New and Nonofficial Remedies 1932, page 19) reads "When the proprietary or trade name for an article is considered insufficiently descriptive of its chemical composition or pharmaceutic character, the Council may require as a condition for the acceptance of such articles that a descriptive scientific name satisfactory to the Council shall appear on the labels, circulars and advertisements for such an article. For all definite chemical substances it is required that the scientific name be given prominence on the label in circulars and advertisements." Under "Proprietary Names for Unoriginal Articles" which follows it is provided that in the case of articles for which the Council has coined a name or for which a name has been adopted in the Pharmacopoeia the N N R or U S P name must appear on labels and in advertising. Although the second sentence quoted is taken by itself provides that the chemical name shall be given for all definite chemical substances the provisions have been interpreted to mean that when a name has been adopted by the Council for such a product or when it has been admitted to the Pharmacopoeia this Council or Pharmacopoeial name must

appear as a synonym and that the chemical name need not appear. To remove the ambiguity of the present provision, the Council voted to revise the sentence "For all definite chemical substances it is required that the scientific name be given prominence on the labels, in circulars and advertisements" to read "For all definite chemical substances it is required that the scientific (chemical) names be given prominence on the labels, in circulars, and in advertisements, provided that for those substances for which there are recognized Council or Pharmacopoeial names, such names shall be used and the scientific name need not appear"

This revision will appear in New and Nonofficial Remedies, 1933

5 Declaration of Composition of Nonmedicinal Articles "Accepted But Not Described"

Under the heading "List of Articles and Brands Accepted by the Council But Not Described in N N R." (New and Nonofficial Remedies, 1932, page 492) the following occurs

Nonmedicinal Articles—Articles which have been examined by the Council which are not advertised as therapeutic agents, the composition of which is sufficiently disclosed to permit judgment as to their harmlessness or safety, and the use of which under ordinary circumstances is, in the opinion of the Council, not contrary to the public welfare

While in accepting these products the Council required that the composition be sufficiently disclosed to permit judgment as to their harmlessness or safety, it has not required that any statement in reference to composition appear in advertisements or in the advertising. In the light of experience it was felt that this was scarcely adequate, since harmlessness or safety would evidently vary with individual cases, which the Council could not prejudge. The Council, therefore, declared that the rule for declaration of composition of accepted medicinal articles should also apply to nonmedicinal articles and voted to revise the statement concerning nonmedicinal articles "Accepted but not Described" to read as follows

Nonmedicinal Articles—Articles which have been examined by the Council which are not advertised as therapeutic agents the composition or essential ingredients of which are quantitatively declared on the label and in the advertising and the use of which under ordinary circumstances is in the opinion of the Council not contrary to the public welfare

This revision will appear in New and Nonofficial Remedies, 1933

BENZYL COMPOUNDS OMITTED FROM N N R

For several years the Council has considered the omission from New and Nonofficial Remedies of benzyl benzoate, benzyl fumarate, benzyl succinate and the various accepted brands of these drugs

Doubt has been expressed by several members of the Council as to whether or not these drugs have any therapeutic value of importance. As a result of the work of Macht, based on the hypothesis that it is the benzyl grouping in the papaverine molecule which determines its smooth muscle effect, there ensued a considerable vogue in the use of benzyl esters in a variety of biologic conditions associated with spasm of the smooth muscle: hypertension, asthma, angina, dysmenorrhea, biliary and renal colic and similar disorders

Benzyl benzoate was first admitted to New and Nonofficial Remedies in 1919. Extensive clinical use of the benzyl esters since that time has not confirmed the promise of therapeutic usefulness. The Council's referee knows of no new evidence presented in the last few years indicating that they have any important value in medicine

Since the period for which all the benzyl compounds listed in New and Nonofficial Remedies were accepted expires with the close of 1932, the referee recommended that they be omitted that the chapter "Benzyl Compounds" be referred to the collected volume of Annual Reports of the Council on Pharmacy and Chemistry as a matter of record and that this statement be adopted for publication

The Council adopted the referee's recommendation and voted to omit the following from New and Nonofficial Remedies: Benzyl Benzoate-Abbott and dosage forms Benzyl Benzoate-Fritzsche Benzyl Benzoate-H W & D and dosage forms Benzyl Benzoate-Mallinckrodt Benzyl Benzoate-Merck Benzyl Fumarate-Abbott and dosage form Tablets of Benzyl Succinate-H W & D and Benzyl Succinate-Merck

Committee on Foods

GENERAL COMMITTEE DECISIONS

THE COMMITTEE ON FOODS AUTHORIZES THE PUBLICATION OF THE FOLLOWING GENERAL COMMITTEE DECISION ADOPTED FOR ITS OWN GUIDANCE AND FOR THAT OF FOOD MANUFACTURERS AND ADVERTISING AGENCIES ON FOOD COMPOSITION AND FOOD ADVERTISING

RAYMOND HERTWIG, Secretary

QUESTIONNAIRE ADVERTISING

Questionnaires addressed to physicians, to members of other professional groups, or to nonprofessional individuals by food manufacturers or their agents, in most instances, do not elicit information of scientific consequence or significance. Questionnaires are of scientific value only when motivated by a sincere desire for truth or unbiased expert opinion rather than by self-centered interests or personal gain and the persons participating are carefully selected and represent those who are scientifically and otherwise qualified to express an unbiased thoroughly scientific opinion in keeping with established knowledge. In all cases, replies to questionnaires will be perfunctory and of little significance unless the replies are from persons whose critique and judgment are entitled to respect.

The use of questionnaires for obtaining information and data from the profession or the public for food advertising purposes is to be discouraged. Such information and data are given undue and unwarranted importance and significance by the public, are misunderstood as to their real value and worth, and therefore are misinformative and misleading.

REPORTS OF THE COMMITTEE

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary

HAPPY JACK SELF RISING FLOUR
(Contains Phosphate, Bicarbonate of Soda and Salt)
(Matured, Bleached)

X-CELLENCE SELF RISING FLOUR
(Contains Phosphate, Bicarbonate of Soda and Salt)
(Matured, Bleached)

Manufacturer—Fant Milling Company, Sherman, Texas

Description—Self rising flours containing blended "hard" and "soft" long patent flours, baking powder (calcium acid phosphate and baking soda) and salt, bleached.

Manufacture—The ingredients are mixed in definite proportions in a batch mixer and automatically packed in cotton sacks. The flour is bleached with a mixture of benzoyl peroxide and calcium phosphate (1 part to 50,000 parts of flour) and nitrogen trichloride (one-ninth ounce per 196 pounds of flour).

Claims of Manufacturer—Self rising flours for home baking of biscuits.

WHITMAN'S CHOCOLATE FLAVORED SYRUP

Manufacturer—Stephen F. Whitman & Son, Inc., Philadelphia

Description—A pasteurized syrup containing water, sucrose, cocoa, invert sugar, salt and vanillin flavor.

Manufacture—The low fat content cocoa, salt and vanillin are worked into a smooth paste with about three fourths of the water of the formula in a mixing kettle, the remainder of the water and sugar are added. The batch is gradually heated to 88 C and pumped into a holding tank. The syrup mixture is passed through a high speed centrifugal clarifier and emulsifier, is homogenized to develop a smooth texture

and consistency, and is automatically packed in jars at 71 C. The sealed jars are pasteurized at 82 C for forty minutes.

Analysis (submitted by manufacturer) —

	per cent
Moisture	33.6
Ash	1.2
Fat	2.1
Protein (N × 6.25)	5.9
Reducing sugars before inversion as invert	9.9
Reducing sugars after inversion as invert	50.6
Sucrose	38.7
Crude fiber	0.9
Carbohydrates other than crude fiber (by difference)	56.3
Theobromine (Wadsworth method)	2.3
Caffeine	0.6

Calories—27 per gram, 77 per ounce

Claims of Manufacturer—A chocolate flavored syrup for the preparation of chocolate flavored milk, hot cocoa or other drinks. Also for dessert dressing, icings, bakings and table uses.

HEINZ STRAINED PEAS (Already Cooked Without Salt or Sugar)

Manufacturer—H. J. Heinz Company, Pittsburgh

Description—Canned comminuted and strained cooked peas retaining in high degree the mineral and vitamin content of the natural product, no added sugar or salt, the coarser fibrous portion is removed.

Manufacture—Selected peas are vined and shelled at the factory. The shelled peas are immediately washed and inspected for removal of foreign material or imperfect peas. No blanching process is used, to avoid loss of any valuable nutrients. The processes of preparation and packing are essentially the same as described for Heinz Strained Spinach (*THE JOURNAL*, Feb 25, 1933, p 577).

Analysis (submitted by manufacturer) —

	per cent
Moisture	84.3
Total solids	15.7
Ash	0.6
Sodium chloride (NaCl)	0.04
Fat (ether extract)	0.5
Protein (N × 6.25)	4.9
Reducing sugars as invert before inversion	0.0
Total reducing sugars as invert after inversion	2.9
Sucrose	2.7
Crude fiber	1.0
Carbohydrates other than crude fiber (by difference)	8.7
Calcium (Ca)	0.01
Phosphorus (P)	0.04
Iron (Fe)	0.001

Calories—0.6 per gram, 17 per ounce

Vitamins—The method of preparation efficiently protects the natural vitamin values. The strained peas is a good source of vitamins A, B and C and a fair source of G.

Claims of Manufacturer—For all table uses of strained peas, but especially intended for infants, children and convalescents and for special smooth diets. Only warming is required for serving. The natural mineral and vitamin values are efficiently retained.

PANTRY WHIPPING CREAM (Sterilized)

Manufacturer—S. M. A. Corporation, Cleveland

Description—Canned sterile homogenized cream of 36 per cent milk fat content.

Manufacture—The process of manufacture is essentially the same as that for Pantry Cream (*THE JOURNAL*, Feb 25, 1933, p 576), with the exception that the cream is standardized to a 36 per cent milk fat content.

Analysis (submitted by manufacturer) —

	per cent
Moisture	58.0
Total solids	42.0
Ash	0.5
Fat (ether extract)	36.0
Protein (N × 6.38)	2.8
Acidity as lactic acid	0.17
Lactose (by difference)	2.5

Calories—3.5 per gram, 99 per ounce

Micro-Organisms—The procedure of manufacture assures a sterile product as shown by the standard methods of bacteriologic analysis of milk of the American Public Health Association.

Vitamins—The vitamin content may be expected to approximate that of the pasteurized cream used.

Claims of Manufacturer—For all table uses of whipping cream.

HEINZ STRAINED CARROTS

(Already Cooked Without Salt or Sugar)

Manufacturer—H J Heinz Company, Pittsburgh*Description*—Canned comminuted and strained cooked carrots retaining in high degree the mineral and vitamin content of the natural product, no added sugar or salt, the coarser fibrous portion is removed*Manufacture*—Carrots grown especially for Heinz Company are topped and run through a mechanical peeler-washer, which removes most of the peel, they are trimmed by hand and any remaining peel is removed by scraping. The trimmed carrots are washed, inspected and placed in a closed cooker. The subsequent treatment and packing are essentially the same as described for Heinz Strained Spinach (THE JOURNAL, Feb 25, 1933, p 577)*Analysis* (submitted by manufacturer) —

Iron (Fe)	0.001

Calories—0.3 per gram 9 per ounce*Vitamins*—The method of preparation efficiently protects the natural vitamin values. The strained carrots is an excellent source of vitamin A, a good source of B and G and a fair source of C*Claims of Manufacturer*—For table uses of strained carrots but especially intended for infants, children and convalescents, and for special smooth diets. Only warming is required for serving. The natural mineral and vitamin values are efficiently retained**FISHER'S YELLOW CORN MEAL**

(Bran and Germ Removed)

Manufacturer—The Fisher Flouring Mills Company, Seattle.*Description*—Finely granular yellow corn meal practically free from corn germ and bran*Manufacture*—Yellow corn is cleaned of foreign seed and materials, scoured and polished, broken between steel rolls and passed through purifiers and aspirators, ground material practically free of germ and bran and of a definite granulation is heat processed to destroy any insect infestation and packed in bags*Analysis* (submitted by manufacturer) —

Calories—3.5 per gram 99 per ounce**SMACO (201) LIQUID PROTEIN MILK***Manufacturer*—S M A Corporation, Cleveland*Description*—A liquid modified milk prepared from milk, cream and soluble casein (sodium caseinate), relatively higher in protein fat and minerals and lower in lactose than whole milk*Manufacture*—Milk complying with amendment No. 9 of the Cleveland Board of Health is pasteurized by the holding system and detatted in a centrifugal cream separator. Calculated quantities of milk fat, the skim milk and soluble casein (sodium caseinate) to produce a 7 per cent milk fat and 4.5 per cent protein mixture are admixed homogenized, canned, sterilized in autoclaves and immediately cooled

The soluble casein (sodium caseinate) is prepared from skim milk. The casein is precipitated with a minimum quantity of chemically pure hydrochloric acid. The supernatant whey is drawn off and the separated casein washed practically free from whey material with water. The washed casein is suspended in

water with just sufficient sodium bicarbonate to peptize the casein. The suspension is agitated until solution is complete. The solution is pasteurized and spray dried

Calories—1.1 per gram 32 per ounce.*Micro-Organisms*—The procedure of manufacture assures a sterile product as shown by the standard methods of bacteriological analysis of milk of the American Public Health Association.*Claims of Manufacturer*—A special food for infant feeding. When diluted according to directions and acidified with lactic acid, its composition conforms closely to Finkelstein's Eiweissmilch. The product is for use under the supervision of the physician, who will provide feeding instructions**FAIRWAY BRAND GOLDEN SYRUP**

(85 Per Cent Corn Syrup, 15 Per Cent Refiners' Syrup)

Packer—Wheeler-Barnes Company, Minneapolis*Distributor*—Twin Ports Wholesale Grocer Company, Superior, Wis*Description*—Table syrup, corn syrup base (85 per cent) with refiners' syrup (15 per cent), the same as Golden Oak Brand Amber Syrup (85 Per Cent Corn Syrup, 15 Per Cent Refiners' Syrup) (THE JOURNAL, Dec 3, 1932, p 1948)**MARTINELLI'S GOLD MEDAL PURE
CONCORD GRAPE JUICE**

(Pasteurized)

Manufacturer—S Martinelli and Company, Watsonville, Calif*Description*—Bottled pasteurized Concord grape juice*Manufacture*—Concord grapes from Eastern propagated vines grown in California are used. They are picked when fully ripe, held over night in a cool well ventilated warehouse, and run through a crusher and stemmer, which breaks the grapes without crushing the seeds and removes the stems. The grape pulp is heated in oak tanks by aluminum steam coils for thirty minutes at a temperature of 51 C, which enables solution of the color of the skins. The pulp is pressed between cloths on wooden racks, the expressed juice is run through a continuous pasteurizer of aluminum steam jacketed pipe and into five gallon glass-carboys (at 82 C), which are sealed while hot and stored in a cool warehouse for six months for clarification purposes. The clear juice is separated from the sediment and pumped to a supply tank, from which it is pumped through a filter consisting of disks of cotton cloth to the filling machine. The bottled and sealed juice is pasteurized for thirty minutes at 73 C*Analysis* (submitted by manufacturer) —

PELLAGRA—A PERSISTENT PROBLEM

Apparently nature cannot always be induced to yield simple answers to legitimate scientific questions. After having been studied for twenty years in the clinic, the field and the laboratory, pellagra still remains a complicated problem. Its literature is too voluminous for any attempt at systematic or documented review. Space permits a mere glimpse at the diversity of the hypotheses that have been suggested. Is pellagra a nutritional deficiency or an infectious disease? The debate on this question, especially between the investigators of the Public Health Service on the one hand and of the Thompson-Macfadden Commission on the other, is well remembered. Jobling and Arnold, however, instead of an answer in terms of one theory, suggested a formulation that comprehends both views and something more beside. According to such an attitude, food faults open the way to an infective organism producing a substance which, more or less deleterious in any case, is so changed by light as to cause the symmetrical skin eruptions typical of pellagra under the influence of Southern sunshine, pellagra sine pellagra could be easily accommodated under the same theory and explained as involving the same pathologic changes except for the lack of sufficient photodynamic influence to develop the skin symptoms.

To the scientific student not directly involved in the controversy as to whether this is a nutritional or an infectious disease, it would seem that while the influence of food is in the great majority of cases predominant, the evidence indicating the possibility of some super-vening infective factor is too strong to be summarily dismissed. More than one epidemiologic study has indicated the spread of the disease after the manner of an infection or its inverse relation to efficient sewage disposal. And while the heroic exposures of the Goldberger group to the various discharges of pellagra patients yielded strikingly negative results, these may perhaps be regarded as balanced by the cases in which pellagra has occurred among people whose food habits were apparently normal but whose resistance may have

been lowered in other ways or overcome by large intakes of pathogens.

Some Southern clinicians also hold that "true" pellagra is a much more pernicious disease than are the great numbers of cases which respond so readily to dietary treatment as to be regarded by them as only "pseudopellagra." However, it now seems to be sufficiently established that pellagra as the term is generally used is so largely preventable by good feeding that for practical purposes it may be regarded as essentially a dietary deficiency disease in the sense that it is usually the nutritional condition of the patient which turns the scale. But is the nature of the nutritional deficiency here involved as clear cut as in the case of scurvy—or even of clinical beriberi, which many oriental physicians are inclined to regard as typically involving an infection superimposed on the vitamin B deficiency? It would seem that the dietary aspect of pellagra cannot be thus simplified unless a part of the evidence is set aside in rather arbitrary fashion or the term pellagra defined more narrowly than in the sense in which it is often used.

A few years ago the protein factor dominated the nutritional discussions of pellagra, and the literature offered what appeared to be fairly good evidence of the potency of certain proteins and even perhaps of certain individual amino-acids in this connection. British investigations of the problem of the prevention of pellagra among Turkish prisoners of war, and the great wealth of contributions from the devoted work of the Goldberger school during the decade 1915-1925, were cast almost entirely in terms of the protein theory. The work of McCollum and his colleagues during the same period indicated that some at least of the "pellagra-producing" diets could be made adequate by enrichment in protein, in certain mineral elements, and in vitamin A. A little later Underhill and Mendel showed that carotene has preventive and curative value in some cases of the pellagra-like black tongue of dogs. As the materials fed by McCollum to augment the intake of vitamin A probably increased the intake of carotene at the same time, the combined contributions from the Yale and the Johns Hopkins laboratories offer rather strong evidence that such fat-soluble substances as natural pigments and vitamin A may (at least in some cases) play an important part in this general problem.

The latter view and that which centered on protein are not necessarily incompatible with each other, if it is granted that the term pellagra in the clinic and the term pellagra-like in the laboratory have been used for a condition or a group of conditions in which the nutritional weakness of the body may be due to shortage of different nutritive factors alternatively, or to a group of such factors any one of which may turn the scale in the individual case. And just as these views are not found to be mutually exclusive, so they are not found to have been disproved by the undoubtedly important

recent work centering on the previously unknown water-soluble substance (or substances) which Goldberger first announced as P-P (pellagra preventive) and later called vitamin G

Rather it would appear that unless much more laboratory evidence to the contrary should be forthcoming, or until the terms pellagra and pellagra-like shall be more narrowly defined than at present, one should at least maintain an open-minded attitude toward the view that the nutritional deficiency which leads to pellagra may be of alternative or multiple rather than simple and invariant nature. This would seem consistent both with the general trend of the evidence and with the most recent contributions to it. Regarding the former it may be said, as was pointed out by the Committee on Nutritional Problems of the American Public Health Association a few years ago, that the one observation that has recurred consistently throughout the conflicting literature of pellagra is the curative and preventive value of milk, which is a good source of all the different nutritional factors that have seemed to be involved. In a contribution by Stiebeling and Munsell¹ from the United States Department of Agriculture, one finds evidence of pellagra preventive value in a number of articles of food which vary so widely in character as to suggest that they might be quite as satisfactorily interpreted in terms of a combination of nutritional factors as of any one alone, and Sherman and Derbigny² of Columbia University offer evidence that the adequacy of the protein intake has a significant bearing on the ability of experimental animals (in this case rats) to endure a shortage of vitamin G. In terms of the Goldberger hypothesis, this has an important possible bearing on the genesis of pellagra.

ENZYMES AND THEIR ACTIVITY

A little over a hundred years ago, Kirchoff observed that malt diastase brought about the same change in starch as was produced by heating with acid and that the hydrolytic agent in one instance the diastase and in the other the acid, apparently remained unchanged at the end of the reaction. In the intervening years, enzymes have been looked on as catalysts, substances that do not initiate or take a permanent part in the reaction but whose presence exerts an influence on the speed of the chemical change. They are considered to be organic in nature, produced only by living cells but not requiring the presence of the cells for their activity. Now, if any of the chemical changes occurring in living organisms are independent of the influence of enzymes, indeed, it has been stated³ that we may regard life as a system of cooperating enzymatic reactions. It is not surprising therefore that this group of substances

should have attracted the attention of investigators in the past or that, under the influence of the newer concepts of biochemistry, there should be a renewed interest in the fundamental nature of enzymes and the mechanism of their action.

For many years, investigators of the enzymes regarded them as proteins. The purest preparations, admittedly far from individual chemical compounds, seemed to be either proteins or substances requiring the presence of protein for their activity. This point of view has received definite support during the past decade. In 1926, Sumner² isolated from the jack bean a globulin which could be crystallized and which is apparently identical with the enzyme urease. Northrop,³ four years later, succeeded in obtaining crystalline pepsin from commercial preparations, these crystals were protein. In 1931, trypsin⁴ and pancreatic amylase⁵ were prepared in crystalline form and in each case the material possessed the physical and chemical characteristics of protein. Subsequent study of the biochemical reactions of urease and of pepsin has led to a mass of convincing evidence pointing to the fact that these enzymes are proteins. However, this view has not gone unchallenged. Employing adsorption methods for the separation and purification of the enzyme preparations, Willstätter¹ and his school contend that they have obtained active enzymes which are not protein in nature and that when, in other enzymes, protein is present, it represents an accompanying or protecting part rather than the active part of the complex. In a recent review, Sumner⁶ has made a vigorous defense of the conception of enzymes as proteins so far as urease and pepsin are concerned, it seems reasonably certain that the protein of the crystals and the hydrolytic potency cannot be dissociated from each other.

How do these organic catalysts act? It has long been known that the enzymes exhibit a remarkable specificity in their reactions, a property independent of the purity of the preparation. Furthermore, enzymatic activity is greatly influenced by factors such as hydrogen ion activity, presence of salts and products of the reaction. The current view of the mechanism of this type of reaction is that the enzyme as well as the substance acted on is responsive to these environmental circumstances, a conception readily explained if these catalysts are proteins. The initial reaction is a chemical combination between enzyme and substrate, then occurs a decomposition with the appearance of the characteristic end products together with the restitution of the enzyme. The initial combination of enzyme with substrate has been shown, in the case of certain proteolytic reactions, to be conditioned by the configuration of the component amino-acids of the peptide as well as by the

effective acidity or basicity of groups adjacent to the primary point of attachment of the enzyme

As emphasized in the recent review of Balls,⁷ many of the newer concepts of the mechanism of enzyme activity have been based on purely artificial systems involving, thus far, mainly decompositions of proteins or simpler peptides. Thus, synthetic peptides are subjected to enzymatic decomposition, and the details of the mode of action are elicited by adjusting the structural features of the substrate. Through the use of these experimental devices, information of fundamental value has been obtained in the immediate past. If life is a series of equilibriums maintained largely through the action of enzymes, recent biochemical research in this field has brought us definitely nearer a more perfect understanding of what life may be.

Current Comment

AMERICAN STUDENTS IN FOREIGN MEDICAL SCHOOLS

Because of the situation created by the matriculation of numerous American students in foreign medical colleges and the difficulties associated with the admission of such students to the examinations of American licensing boards, special consideration was given the subject by the Federation of State Medical Boards in its annual session in Chicago, February 14. At this time, according to the secretary, Dr. Walter L. Bierring, the following recommendations were adopted:

1 That no American student matriculating in a European medical school subsequent to the academic year 1932-1933 will be admitted to any state medical licensing examination who does not, before beginning such medical study, secure from a state board of medical examiners or other competent state authority a certificate, endorsed by the Association of American Medical Colleges or the Council on Medical Education and Hospitals of the American Medical Association, showing that he has met the premedical educational requirements prescribed by the aforementioned association.

2 That no student, either American or European, matriculating in a European medical school subsequent to the academic year 1932-1933 will be admitted to any state medical licensing examination who does not present satisfactory evidence of premedical education equivalent to the requirements of the Association of American Medical Colleges and the Council on Medical Education and Hospitals of the American Medical Association, and graduation from a European medical school after a medical course of at least four academic years, and submit evidence of having satisfactorily passed the examination to obtain a license to practice medicine in the country in which the medical school from which he is graduated is located.

These recommendations had been previously endorsed by individual state medical licensing boards. The American student, therefore, who goes abroad to complete his medical education will do well to get in touch with the medical licensing board of the state in which he eventually intends to practice or with the Council on Medical Education and Hospitals before spending money and time or he may find that he has made an

error that will require years of study and additional expense to correct. The second recommendation serves to prevent exploitation of American students by some foreign medical schools. Obviously, the purpose of these resolutions is to safeguard the practice of medicine in the United States and to maintain the high standards of medical education that now obtain in this country.

THE BLOOD PLATELETS

Much attention is being directed at present to the various types of cells that circulate in the blood. Differentiation of the cells, both of the colored and the colorless variety, is proceeding effectively. The blood count of today calls for something more than an enumeration of the total number of "red" and "white" cells in a specified unit volume of blood. The apparatus employed is being improved, the technic of measurement is becoming more refined. The value of the results obtained depends on the establishment of certain norms within the broad limits of which the figures for good health are included. In the case of the erythrocytes the normal ranges of their concentration in the blood have become well standardized. The errors in making the "blood counts" and possible deviations from the "average" are generally recognized. This is by no means equally true of the blood platelets, the enumeration of which becomes important in the study of the hemorrhagic diseases. This is particularly true in purpura hemorrhagica and, as a recent writer¹ states, is also of great interest and probably of more value than is realized in the study of anemias, leukemias and associated disorders. Since the blood platelets are derived from the megakaryocytes of the bone marrow, he adds that they should give, in association with a study of the number of reticulocytes and neutrophils, a complete index as to the activity of the marrow. A widely used American textbook of physiology records the average number of platelets as 300,000 per cubic millimeter, adding that the extremes reported vary from 200,000 to 778,000. A popular British textbook fails to designate any figure. The discrepancies in the scientific literature are undoubtedly considerable. Dameshek¹ remarks that the chief difficulty encountered in the enumeration of the blood platelets depends on the marked tendency of these bodies to clump together. This difficulty has often led to neglect of this valuable laboratory procedure. His review of some records of the average number of blood platelets per cubic millimeter of normal persons, as determined by six recognized methods, includes the following figures: 234,000, 297,000, 300,000, 469,000, 536,000, 619,000. As the result of his own elaborate investigations at the Beth Israel Hospital in Boston, Dameshek reports that the mean blood platelet count found for men was 716,000 per cubic millimeter, the median count, 710,000 per cubic millimeter. Fifty-five per cent of the counts were between 600,000 and 800,000 per cubic millimeter.

¹ Dameshek, William. A Method for the Simultaneous Enumeration of Blood Platelets and Reticulocytes, *Arch. Int. Med.* 50: 579 (Oct) 1932.

and 84 per cent were between 500,000 and 900,000 per cubic millimeter. The normal range for men is probably represented by the latter figure. The normal count in women is made uncertain by the complicating presence of the menstrual cycle. The intermenstrual range is from 400,000 to 800,000 per cubic millimeter. According to Dameshek the experimental error is probably not greater than 70,000 per cubic millimeter when the erythrocyte count is normal and not more than 10,000 per cubic millimeter when the erythrocyte and blood platelet counts are very low. The new method permits the simultaneous enumeration of the blood platelets and the reticulocytes, and depends on the use of an isotonic, anticoagulating solution containing the "vital" dye brilliant cresyl blue. The platelets are examined under an oil immersion lens. The estimation of the reticulocytes likewise is becoming a necessity in clinical hematologic diagnosis.

AWARDS AND RECOGNITIONS IN CHEMISTRY AND IN MEDICINE

One of the debated points in the field of science is the value of prizes, awards, medals, certificates of merit, or similar trophies in stimulating research or in establishing in the public mind the value of exceptional scientific results. Readers of *THE JOURNAL* are, no doubt, familiar with the numerous recognitions of this character now existing in the field of medicine. The American Medical Association itself has established medals and certificates as awards conferred annually in the Scientific Exhibit. There are such prizes as the Nobel Prize, the Cameron Prize, the Alvarenga Prize and many others which recognize contributions of extraordinary merit. Recently Prof. John J. Abel of Johns Hopkins University received the Conne Medal, awarded annually to an individual responsible for a discovery in chemistry which proves of value in medicine. This medal is awarded by a jury selected by the Chemists' Club of New York from among the leaders of both the chemical and medical professions and was instituted primarily with the underlying purpose of bringing the medical and chemical professions closer together in a common effort to render aid to suffering humanity. The work of Dr. Abel in isolating active principles of glandular organs and other tissues has been mentioned repeatedly in these columns. In contrast with what may be considered a well merited award to a man who has received numerous other awards in recognition of his work is the recent award of a medal by the New York section of the American Chemical Society to Prof. Wilder Bancroft for his extraordinary views on the effects of sodium thioacetate and for his theory of agglomeration—or maybe it is conglomeration—in relationship to the treatment of certain types of mental disease. To the physician this seems to be a premature acceptance of an unestablished hypothesis and of a method of treatment for which there is not the slightest scientifically controlled evidence. Obviously, incidents of this type cast doubt on the whole system of rewards and prizes in the field of scientific research and discovery.

Association News

ABSTRACT OF MINUTES OF MEETING OF BOARD OF TRUSTEES HELD AT HEADQUARTERS, CHICAGO, FEB 16 AND 17, 1933

A meeting of the Board of Trustees was held at Association headquarters, Chicago, Feb 16 and 17, 1933, and the following actions were taken:

EDITORIAL ON INCREASE IN COST OF GERMAN PERIODICALS

At the request of the Chairman of the Committee on the Cost of Current Medical Periodicals, appointed by the American Library Association, the Board of Trustees authorized the publication in *THE JOURNAL* of an editorial in regard to the publication and comparative costs of medical periodicals.

COMMITTEE TO PREVIEW MOTION PICTURES

With the cooperation of the Medical Society of the County of New York and of the Los Angeles County Medical Association, the Board has appointed two committees to advise producers of motion pictures regarding the details of pictures having a bearing on medicine. The personnel of these committees is: Drs. Charles T. Sturgeon, John Vruwink and Harry H. Wilson of Los Angeles, and Drs. Peter Irving and David J. Kaliski of New York City.

EXTENSION OF CREDIT TO PHYSICIANS

The Board authorized that *THE JOURNAL* be continued to subscribers who, on account of being temporarily embarrassed, are more than a year in arrears in their payments, provided a promise to remit is received from them.

COMMITTEE ON FOODS

Drs. Mary S. Rose, New York, and James McLester, Birmingham, Ala., were added to the Committee on Foods, and the terms of service of the several members were fixed as follows: Drs. Hess and Bailey, to expire in 1934; Drs. Fishbein and Powers, 1935; Drs. Wilder and Mendel, 1936; Drs. Jeans and Rose, 1937, and Dr. McLester, 1938.

TRAINING OF MEDICAL OFFICERS IN THE RESERVE OFFICERS' TRAINING CORPS

In view of the fact that, so far as can be learned, it is not proposed to effect any saving by the proposed elimination of military training for physicians, dentists and veterinarians, but that the total amount to be appropriated is to remain the same as has been asked for by the War Department for the maintenance of the Reserve Officers' Training Corps, which covers military training for physicians, dentists and veterinarians, and in view also of the fact that the discontinuance of this training would mean a regrettable loss to the Medical Department since the Medical Department R. O. T. C. units constitute the principal source of recruitment not only for the various sections of the Medical Department Officers' Reserve Corps but also of the Medical Department of the Regular Army, the Bureau of Legal Medicine and Legislation was authorized to cooperate with the Surgeon General of the Army in his efforts to maintain Medical Corps, Dental Corps and Veterinary units in the Medical Officers' Training Corps.

LIMITATION OF RETIRED MEDICAL OFFICERS BY APPROPRIATION BILL

The Bureau of Legal Medicine and Legislation was also instructed to endeavor to protect the interests of retired medical officers.

HOMOLOGOUS LEGISLATION IN REGARD TO PAY FOR FLIGHT SURGEONS

The Board further approved cooperation with the Surgeon General of the Navy in an endeavor to procure for the officers and men in the Medical Corps extra compensation for aerial service corresponding to the extra compensation paid officers and men in other corps of the Navy when similarly engaged.

QUARTERLY CUMULATIVE INDEX MEDICUS

Consideration was given to suggestions that two, instead of four, issues a year of the *Quarterly Cumulative Index Medicus* be published, and that the cumulative feature be eliminated. After careful deliberation, however, it was felt that the adopting of either or both of these suggestions would impede the progress of research and handicap particularly the persons for whom the index is primarily published, and it was decided to continue the index in its present form.

DISCONTINUATION OF AFFILIATION WITH ASSOCIATION
PROFESSIONELLE INTERNATIONALE DES MÉDECINS

It was decided to discontinue affiliation with the Association Professionelle Internationale des Médecins because of the present unfavorable economic conditions and also because, owing to the fact that there are fifty-four major governmental units of the United States, in addition to the federal government and to approximately 3,100 county units, and that each state and territory has its own law-making bodies, it is impossible to cooperate to the fullest extent with the Association Professionelle Internationale des Medecins by answering its questionnaires.

RESOLUTION FROM THE MEDICAL SOCIETY OF THE
STATE OF PENNSYLVANIA RELATIVE TO
MEDICAL PRACTICE

The following preambles and resolution adopted by the Board of Trustees of the Medical Society of the State of Pennsylvania at its meeting in Harrisburg, Dec 6, 1932, were approved:

WHEREAS, There have been formed important national organizations of physicians, specialists, other than the American Medical Association, and

WHEREAS, Such organizations fundamentally formed for scientific purposes have from time to time publicly expressed opinions concerning the entire practice of medicine, especially in its social and economic relationships, and

WHEREAS, An unusual emphasis on the social and economic position of medical practice has recently been precipitated by the published report of the national committee known as the Committee on the Costs of Medical Care, be it

Resolved, That, in the interest of the welfare of the public and the maintenance of the most serviceable form of medical practice, the proper representatives of the American Medical Association request other national medical organizations whose qualifications for membership include membership in the American Medical Association to publicly declare their opinions on general social, legislative and economic relationships of medical practice only through approved channels of the American Medical Association. To this end the Board of Trustees of the Medical Society of the State of Pennsylvania pledges its own efforts and influences to bring about this most desirable point of view in the minds of the members of the Medical Society of the State of Pennsylvania, who are also members or Fellows of the other organizations referred to. They also respectfully request the Board of Trustees of the American Medical Association to bend every effort to accomplish this purpose throughout the Association at the earliest possible moment in order that the sane evolutionary progress of medical practice may not be disturbed by social experiments which endanger the health and the welfare of our citizenship, and which have proved a pernicious health influence in other nations.

APPOINTMENT OF REPRESENTATIVES

The following appointments were made: Dr Dean Lewis, President of the Association, to represent that body at the meeting of the British Medical Association, to be held in Dublin, July 25-28, 1933; Dr W W Bauer, to act in an advisory capacity to the Advisory Committee to the 4-H Health Movement; Dr Albert Soland, to represent the Section on Radiology of the American Medical Association at the Fourth International Congress of Radiology, to be held in Zurich in 1934; and Dr Thurman Rice of Indianapolis to succeed Dr Orlando H Petty (deceased) on the Joint Committee on Health Problems in Education of the American Medical Association and the National Education Association.

TERMS OF SERVICE OF MEMBERS OF COUNCIL
ON PHYSICAL THERAPY

The terms of service of the members of the Council on Physical Therapy were fixed as follows: Drs Desjardins and Williams, to expire in 1933; Drs Pemberton, Mock and MacKee, 1934; Drs Garrey, Coblentz and Coulter, 1935; and Drs Osgood, Gaenslen and Karsner, 1936.

AMERICAN MEDICAL DIRECTORY

Authorization was given for a canvass of subscribers to the Directory to ascertain whether or not a new edition is desired.

ANNA FULLER MEMORIAL PRIZE

The Board gratefully received notification of the fact that, in the will of the late Egbert C Fuller, provision is made for an award, or awards, of a suitable sum out of the income of the Anna Fuller Fund to such person or persons as shall at any time within successive periods of five years each, commencing one year after his death, make a real and outstanding contribution to knowledge on the subject of cause, care, prevention or cure of cancer. The award, or awards, according to the provisions of the will, are to be made on the recommendation of the President of the American Medical Association, the Dean of the Johns Hopkins Medical School and the Dean of the Harvard Medical School, and on such terms and conditions as Mr Fuller's trustees shall fix.

ELECTIONS

Nominations to fill vacancies on the editorial boards of the special journals, on councils and on committees were considered, and the following appointments were made:

Drs Louis Casamajor, Martin F Engman, Chevalier Jackson, E Starr Judd, Walter R Parker, and L R DeBuys were elected to succeed themselves on the editorial boards of the *Archives of Neurology and Psychiatry*, *Archives of Dermatology and Syphilology*, *Archives of Otolaryngology*, *Archives of Surgery*, *Archives of Ophthalmology* and *American Journal of Diseases of Children*, respectively. Dr George M Coates was elected to succeed Dr George Fetterolf (deceased) on the editorial board of the *Archives of Otolaryngology*, and Dr Victor C Jacobson to succeed Dr W G MacCallum on the editorial board of the *Archives of Pathology*.

Dr J J Morton was elected to succeed himself on the Committee on Scientific Research, and Drs R A Hatcher, H N Cole and E E Irons to succeed themselves on the Council on Pharmacy and Chemistry.

MISCELLANEOUS

Appropriations were made to carry on the work of the various councils and bureaus, as well as for the Committee on Scientific Research and the Committee on the Protection of Medical Research. Attention also was given to other matters, more or less routine, many of which will receive further consideration at a later date.

MEDICAL BROADCAST FOR THE WEEK
American Medical Association Health Talks

The American Medical Association broadcasts on Monday and Wednesday from 9 45 to 9 50 a m (central standard time) over Station WBBM (770 kilocycles, or 389.4 meters).

The subjects for the week are as follows:

March 6 Faith in Food Advertising
March 8 A Life for Ten Dollars

There is also a fifteen minute talk sponsored by the Association on Saturday morning from 9 45 to 10 o'clock over Station WBBM.

March 11 Scientific Experiment and Medicine

The Adrenal Cortex—The adrenal glands were first described in 1563 by Eustachius, but up until the middle of the nineteenth century they were chiefly objects of curiosity to anatomists and excited little interest among members of the medical profession. However, in 1855, following the publication by Thomas Addison of the classical paper describing the disease which now bears his name, these glandular structures came into prominence. Since this time they have played an important, if somewhat doubtful role, in the speculations and theories of experimental biologists and clinicians. The discovery of adrenalin and study of its interesting pharmacodynamic properties in the early years of the present century greatly stimulated experimental and clinical work on the adrenals, and as a result careful investigation soon established the fact that it is the cortex of the gland that is essential for life, and not the medulla or adrenalin secreting portion—Swingle, W W, and Pfiffner J J. *The Adrenal Cortical Hormone, Medicine* 11 372 (Dec) 1932.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARIZONA

Bill Introduced—S 110 proposes to require all applicants for licenses to marry to present physicians' certificates stating that both parties to the proposed marriages do not have tuberculosis in the infectious stages and have not been adjudged by courts of competent jurisdiction to be of unsound mind and that the male parties do not have venereal disease.

ARKANSAS

Bill Introduced—S 322 proposes to authorize city councils to levy annual occupational taxes on all practitioners of the healing art.

CALIFORNIA

Beaumont Exhibit—To commemorate the centenary of the publication of William Beaumont's (1785-1853) "Experiments and Observations on Gastric Juice and Digestion," in Plattsburg, 1833, an exhibit has been arranged in the library of the University of California Medical School. The first edition of this physiologic classic is on view together with a number of other editions of the work, and with other material relating to Beaumont, *California and Western Medicine* reports.

Tuberculosis Meeting—The annual meeting of the California Tuberculosis Association will be held at the Hotel Coronado, Coronado, March 10-11. On the program will be the following physicians:

Emor H. Christopherson, San Diego, Does the Preventorium Prevent Tuberculosis?

John N. Force, Berkeley, Racial Tuberculosis—Epidemiological Problems.

Leland G. Hunnicutt, Pasadena, Bronchoscopy in Tuberculosis.

Percy K. Telford, Los Angeles, Mexican Tuberculosis Problem.

Edwin S. Bennett, Los Angeles, Criteria of Diagnosis in U. S. Veterans.

Rudolph H. Sundberg, San Diego, Adolescent Tuberculosis.

Hans Lusser, San Francisco, Relation of Endocrine System in the Development of Treatment of Tuberculosis.

Emil Bogen, Olive View, Progress in Tuberculosis Research.

Philip H. Pierson, San Francisco, Evaluation of Laboratory Tests in Determining Activity in Tuberculosis.

Leroy H. Briggs, San Francisco, Nonpulmonary Tuberculosis.

Health education will be discussed by Drs. James Houloose, Long Beach; Walter M. Brown, San Francisco; Jay D. Dunshie, Pasadena; and Mr. Paul Edwards, editor-in-chief of the *San Diego Sun*. Papers considering the early diagnosis of tuberculosis will be presented by Drs. Ethel D. Owen, San Francisco; Roscoe C. Mann, Santa Barbara; Arthur Hieronymus, Oakland; and Miss Mary Stanton, Los Angeles. Drs. William H. Park and Camille Kereszturi, both of New York, will address an evening session on BCG Immunization.

CONNECTICUT

Bill Introduced—H 1079 to amend the workmen's compensation act proposes to permit chiropractors to render the medical treatment which employers must supply their injured employees.

GEORGIA

Society News—The Ben Hill County Medical Society and the state department of health sponsored a traveling tuberculosis clinic, February 2-3.—Dr. David T. Smith, Durham, N. C., addressed the 14th District Dental Society, and the Fulton County Medical Society, February 21, on Relation of Fissure Spirochetal Organisms of the Mouth to Trench Mouth, Pyorrhea, Bronchiectasis and Lung Abscess.

Bills Introduced—S 142 to amend the medical practice act proposes to eliminate that provision directing the board to elect a secretary-treasurer from its membership so as to conform with the terms of the act of 1931 approved August 29 providing for a joint secretary of the several state examining boards. The bill proposes also that members of the board be paid a \$15 per diem and all necessary expenses incident to holding board meetings. S 155 to amend the pharmacy practice act proposes to require all applicants for registration as pharmacists to be graduates of schools of pharmacy recommended by the board of pharmacy and in addition to have twelve months of practical experience in a place where the duties of pharmacist are performed by licensed pharmacists.

Under the present law, applicants can be licensed after examination if they have had thirty-six months' actual experience in a pharmacy or have graduated from a school of pharmacy.

IDAHO

Bill Passed—S 99, to prohibit the possession, sale or distribution of "anhalonum, otherwise known as peyote," has passed the senate.

ILLINOIS

Bills Introduced—H 325 proposes to eliminate those provisions in the medical practice act authorizing the licensing of midwives. H 326 proposes to require both parties to proposed marriages to present certificates from licensed physicians that they are free from venereal disease.

Public Health Council Organized—The establishment of a public health council in De Witt County has been announced as the outgrowth of a diphtheria prevention campaign sponsored about a year ago by the De Witt County Medical Society. Membership is open to physicians who are members of the county medical society, officials of the schools, and two representatives of any other organization in the county interested and willing to participate in the activities and purpose of the council. A broad public health program will be carried on through committees.

Chicago

Hospital Anniversary—More than 200 members and friends of the woman's board of the Presbyterian Hospital gathered at the hospital, January 9, to commemorate the fiftieth anniversary of the institution. It was reported that, including the admissions of that day, 280,489 patients had been hospitalized since the hospital opened, of these, 83,496 were entirely free. The family of the founder of the hospital, Dr. Joseph P. Ross, was represented by Mrs. Frederick T. Haskell, a daughter. The first ambulance of the hospital was supplied by the woman's board.

Drs. Dick Awarded Cameron Prize—The Cameron Prize for 1933 has been awarded jointly to Drs. George F. Dick, professor of medicine and chairman of the department of medicine, Division of Biological Sciences, University of Chicago, and Gladys H. Dick of the John McCormick Institute for Infectious Diseases, in recognition of their work on the etiology and treatment of scarlatina. This award is made annually by the University of Edinburgh, Scotland, on the recommendation of its faculty of medicine. The prize amounts to about \$685 (at the present rate of exchange) and is given annually "to a person who, in the course of the five years immediately preceding, has made any highly important and valuable addition to practical therapeutics." Other Americans who have been given the award include Dr. Harvey Cushing, 1924, and Dr. George R. Minot and Dr. William P. Murphy, Boston, 1930.

INDIANA

Bill Introduced—S 277 proposes to accord hospitals treating persons injured through the fault of other persons liens on all rights of action claims, judgments, settlements or compromises accruing to the injured persons because of their injuries. This lien however is not to attach to claims under the workmen's compensation act.

Personal—Dr. Wilber F. Dunham, formerly of Kempton, has been appointed superintendent of the school for feeble-minded youth at Fort Wayne. He will also be head of the Muscatatuck Colony for epileptics, Butlerville, it is reported.—Dr. Marcus W. Lyon, Jr., South Bend, was recently elected president of the Indiana Academy of Science.—Dr. Robert B. Sanderson, Crown Point, has been appointed superintendent of Healthwin Hospital, South Bend, succeeding the late Dr. St. Clair Darden.—Dr. Jesse W. Bowers, Fort Wayne, was elected president of the Indiana State Board of Registration, January 11.

KANSAS

Bills Introduced—H 629 proposes to permit physicians to possess and prescribe intoxicating liquor under the same general restrictions that are imposed by the federal law. S 458 proposes that no patient be admitted to any dispensary of the University of Kansas School of Medicine unless a licensed doctor of medicine certifies that the patient is unable to pay for medical services. S 498 to amend the medical practice act proposes (1) to require licensees to register annually with the secretary of the board of medical registration and examination and to pay annual fees of \$1 (2) to make the secretary of the board the custodian of a common seal and of the books.

and records of the board, and (3) to make the records and the register of the board prima facie evidence in courts of law of all matters recorded therein. H 517 proposes to authorize the board of dental examiners to license persons to practice as dental hygienists. S 465 proposes to require all applicants for licenses to marry to present certificates from licensed physicians stating that the parties to the proposed marriages are free from mental and venereal disease.

MASSACHUSETTS

New Commissioner of Mental Diseases—Dr James V May, Boston, has been appointed commissioner of the department of mental diseases, state department of health, succeeding the late Dr George M Kline. Dr May has been superintendent of the Boston State Hospital since Dec. 1, 1917. He is now president of the American Psychiatric Association.

Club Observes Fiftieth Anniversary—The Brookfield Medical Club, the second oldest independent medical club in the state, reached its fiftieth anniversary, Nov 23, 1932. At an anniversary celebration earlier in the year Dr John Richard Fowler, Spencer, described its history. Seven physicians organized it in 1882 at the home of Dr Albert G Blodgett, Ware, the first secretary of the organization. Dr Edgar H Guild, Springfield, who joined the club in its first year, is the oldest living member. Dr Blodgett, the founder, was president of Hampshire County Medical Society, 1904-1905, and for six years president of the board of health of Ware.

Sunday Public Lectures—A course of free public lectures on medical subjects by the faculty of Harvard University Medical School on Sunday afternoons began, January 15, with an address by Dr William B Castle on anemia. Other lecturers were Drs George H Bigelow, January 22, on the depression and health; Walter B Lancaster, January 29, sparing the eyes; Gustave P Grabfield, February 5, rheumatism; George H Wright, DDS, February 12, color changes in the mouth and teeth; an aid in diagnosis of systemic disease; and Dr Henry R Viets, February 26, nerve, nerves and nervousness. Subsequent speakers and their subjects will be

Dr Everard L Oliver, March 5, the care of the skin and scalp
Dr Shields Warren, March 12, cancer and radiation therapy
Dr Randall Clifford, March 19, the tuberculosis problem today
Dr Wilson G Smilie, March 26, a discussion of the common cold

MICHIGAN

Society Presents Plays—Two one act plays were presented, January 14, by members of the Wayne County Medical Society and their wives. The titles of the plays were "The Music Cure," by G Bernard Shaw, and "The Vahant," by Holworthy Hall and Robert Middlemass. Music was furnished by the Noon Day Study Club trio.

Memorial to Dr Burgess—A bronze tablet was unveiled in the Wayne County Coroners' Court Building, Dec 20, 1932, to the memory of Dr James E Burgess, for twenty years coroner of the county, who died last year. The tablet, which was unveiled by Dr Jay M Burgess, the brother of Dr Burgess, was the gift of officials and employees of the coroner's office. Speakers at the ceremony included Drs H Wellington Yates, president of the Wayne County Medical Society, and Albert L French.

Society News—Icie G Macy, Ph D, Detroit, addressed a joint meeting of the Wayne County Medical Society and the Detroit District Dental Society, February 14, on "The Application of Nutrition to Medicine and Dentistry."—Allan W Rowe, Ph D, Boston, addressed a joint meeting of the Wayne County Medical Society and the Detroit Obstetrical and Gynecological Society, February 7, on "Constitutional Influences in Human Infertility."—Dr Sam Z Levine, Flushing, N Y, addressed the Detroit Pediatric Society, January 11, on "Metabolism in Infants."

MINNESOTA

Bills Introduced—H 203, to amend the law regulating massage, proposes to exempt from the provisions of the law "institutions where massages are given as a part of a treatment under the direction of a licensed physician." S 291 and H 531 propose to create a board of naturopathic examiners and to regulate the practice of naturopathy. Applicants for such licenses must pass examinations to be given by the board of basic science examiners before presenting themselves to the naturopathic board for examination. H 598 proposes to accord hospitals treating persons injured through the fault of other persons liens on all causes of action accruing to the injured persons because of their injuries.

NEBRASKA

Survey of Health Service—Dr Leslie L Lumsden of the U S Public Health Service, at the request of the health commissioner of Omaha, the Douglas County Board of Commissioners and the state health director, made a survey in December, 1932, of health service and of medical and surgical care of the indigent in Douglas County. Separation of public health activities and relief activities was Dr Lumsden's first recommendation. He then recommended the appointment of a full time health officer to serve both the city of Omaha and Douglas County, even if it should be necessary to amend state laws to effect the arrangement, and adequate appropriations on a scale of 50 cents or more per capita. To carry on the medical, surgical and dental relief of the indigent, Dr Lumsden suggested the creation of a county board of ten members, including the deans of the Creighton and University of Nebraska medical schools, the mayor of Omaha, the chairman of the county board of commissioners, two members of the Omaha-Douglas County Medical Society, and representatives of the Omaha District Dental Society, the Chamber of Commerce, the Omaha Bar Association and the council of social agencies. A full time county physician should be appointed with headquarters and facilities at the Douglas County Hospital, the report states. He also recommended the provision of more beds for hospitalization of indigents, especially at the county hospital, and the provision of space for operating rooms there. A suggestion was that health work in the public schools, now under the jurisdiction of the board of education, be merged in the activities of the county-city health department. Finally he advised that the county medical and dental societies and other interested organizations appoint special committees to cooperate with the health department and the hospital board when they are organized.

NEVADA

Bill Introduced—S 61 proposes to repeal the law regulating the possession and distribution of narcotic drugs and to enact the uniform narcotic drug act.

NEW HAMPSHIRE

Bills Introduced—S 21 proposes to amend the provisions of the food and drug law with respect to misbranding, so as to include cosmetics and disinfectants, and so that labels need not bear statements of the quantity or proportion of alcohol contained in the packages to which they are affixed. S 20, to amend the workmen's compensation act, proposes to increase from fourteen days to thirty days the period during which an employer must furnish reasonable medical and hospital services to an injured employee.

NEW JERSEY

Personal—Dr John V Smith, Perth Amboy, has been appointed a member of the state board of institutions and agencies.

Bill Introduced—A 170, to supplement the chiroprody practice act, proposes to define chiroprody as "the examination, diagnosis, or treatment of any ailment of the human foot, by surgical, medical, mechanical, electrical or physical means."

Graduate Lectures—The Medical Society of New Jersey in cooperation with Rutgers University has recently presented a course of lectures on recent advances in medicine and surgery for members of the Union County Medical Society in Elizabeth. The lecturers and their subjects were

Dr John A. Kolmer, Philadelphia, pneumonia therapy
Dr Temple S. Fay, Philadelphia, cerebral injuries
Dr William Goldring, New York, renal diseases
Dr Thomas McCrae, Philadelphia, hypertension and hypotension
Dr William Wayne Babcock, Philadelphia, recent advances in surgery
Dr Henry L. Bockus, Philadelphia, diseases of the liver

NEW MEXICO

Bills Introduced—H 169 proposes to require the board of pharmacy to issue, without examination, certificates of registration to licensed physicians owning or operating drug stores. H 179 proposes to require the boards of county commissioners to provide medical attention for the indigent sick in their counties. H 220 proposes to require county health officers to furnish medical treatment without charge to the indigent sick in their counties. H 207 proposes that no physician employed on a full-time basis by the United States government in any United States government hospital, reservation, sanatorium or other institution shall practice medicine on any one in the state not a patient in said hospital, reservation, sanatorium or institution.

NEW YORK

Bills Introduced.—S 1043 proposes to repeal the laws relating to the possession and distribution of narcotic drugs and to enact the uniform narcotic drug act. A 1150 proposes to make it a misdemeanor for any person to prepare, dispense or sell any drug or medicine which does not have affixed on the bottle or container a label stating the name of the drug and the name and quantity of each ingredient composing it. The bill, however, is not to apply to preparations prescribed by a licensed physician, dentist or veterinarian.

Health at Utica.—Telegraphic reports to the U S Department of Commerce from eighty-five cities with a total population of 37 million, for the week ended February 18, indicate that the highest mortality rate (19.2) appeared for Utica and the rate for the group of cities as a whole, 12.4. The rate for Utica for the corresponding week of 1932 was 9.7 and that for the group of cities, 12.5. The annual rate for the eighty-five cities for the seven weeks of 1933 was 12.7 as against a rate of 12 for the corresponding period of the previous year. Caution should be used in the interpretation of weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for a large area or that they have a large Negro population may tend to increase the death rate.

New York City

Brickner Lecture.—Dr Alfred W Adson, Rochester, Minn, presented the third annual Walter M Brickner Lecture at the Hospital for Joint Diseases, February 23, on "The Physiological Effect of Sympathectomy in Treatment of Peripheral Vascular Diseases, Hirschsprung's Disease and Cord Bladder."

Nurses' Training School Discontinued.—The New York Post-Graduate Medical School and Hospital announced, February 6, that its school of nursing would be discontinued in March. The present student body will remain to be graduated, but new students will not be accepted. Plans for graduate training of nurses will probably be formulated during the coming year, the announcement stated. The action is said to have been prompted by the reports of the Committee on Grading of Nursing Schools, which have shown that the profession is overcrowded. The school of nursing is the third oldest in New York, having been organized in 1885.

University News.—A discussion course on medical sociology was recently begun at Long Island College of Medicine by Dr James P Warbasse. The course, which is compulsory for second year students, is designed to stimulate medical students to realize the relationship of the physician to the profession and to society. Graduates of Georgetown University Medical School Washington, D C, resident in and near New York, organized a New York chapter of the Georgetown University Society at a recent meeting at the New York Post-Graduate Medical School and Hospital. Dr John P Ruppe was elected president and Dr John W Mahoney, Bayside, secretary.

NORTH DAKOTA

Bill Introduced.—H 270 apparently proposes to permit any person to practice obstetrics or midwifery after filing a certificate in the office of the register of deeds of the county in which he desires to practice stating that the person desires to practice obstetrics or midwifery.

OHIO

Bill Introduced.—H 201 proposes to create a board of chiropractic examiners and to regulate the practice of chiropractic. Chiropractic is defined as the art and science of locating, and adjusting by hand the subluxations of the articulations of the human spinal column which is deemed to be the twenty-four movable vertebrae including the sacrum and coccyx and adjacent tissues for the purpose of removing any interference with nerve transmission but it shall not include major surgery nor the administration or prescription [sic] of any drug or medicine included in materia medica.

Society News.—Dr Russell H Birge was elected president of the Cleveland Medical Library Association at the annual meeting January 20 to succeed Dr George E. Follansbee. Dr Clyde I. Cummer was re-elected chairman of the board. Dr Carl H. Lenhart, director of the library and Dr Thomas P. Shippey, secretary. The annual report showed that the registration of readers for the year was 12,840 and that the library now has 50,211 books and bound journals. The society has 692 members. —Dr William L. Galle, Toronto, Ont. and Dr J. L. B. had addressed the Cleveland Academy of Medicine

February 17, on "Appendicitis in Childhood" and "Surgical Treatment of Peptic Ulcer," respectively.—Dr Thomas B. Magath, Rochester, Minn., addressed the Toledo Academy of Medicine, February 3, on "Parasitology—A Study of Animal Parasites." Dr Max Ballin, Detroit, addressed the academy, January 7, on surgical treatment of the parathyroid gland.

OKLAHOMA

Bill Introduced.—H 199 proposes to prohibit licensed physicians from charging fees in excess of 25 cents per mile for making professional calls. Any physician violating the provisions of the bill is to be guilty of a misdemeanor and to be fined not less than \$25 nor more than \$100.

OREGON

State Board Elects Officers.—Dr Norman E. Irvine, Lebanon, was recently elected president of the state board of health, Drs Albert Mount, Oregon City, vice president, and Frederick D. Stricker, Portland, secretary.

Bill Introduced.—S 280 proposes to make it unlawful for the state industrial accident commission or any employer to enter into any contract for first aid or medical service to injured workmen, except with licensed physicians.

Departments Consolidated.—The departments of obstetrics and gynecology of the University of Oregon Medical School, heretofore separate, have been combined since the death of Dr Clarence J. McCusker, clinical professor of obstetrics, and Dr Raymond E. Watkins, now clinical professor of gynecology, has been appointed professor and head of the department of obstetrics and gynecology, according to an announcement by Dr Richard B. Dillehunt, dean.

PENNSYLVANIA

Bill Introduced.—H 534 proposes to authorize the department of health to license persons to practice beauty culture. Such licensees are to be permitted, among other things, to remove superfluous hair from any part of the female body.

Philadelphia

Beaumont Centenary Meeting.—The section on medical history of the College of Physicians of Philadelphia held a special meeting, February 13, in commemoration of the one hundredth anniversary of William Beaumont's historic work on digestion. Speakers on Beaumont were Drs Walter R. Steiner, Hartford, Conn., "Dr William Beaumont: A Sketch", Julius Friedenwald, Baltimore, "Beaumont's Work as Related to Gastro-Enterology," and Isidor S. Ravdin, "Beaumont's Work as Related to Surgery."

Dr Bond Honored.—The Philadelphia Award, consisting of a gold medal, a scroll of honor and a check for \$10,000, was presented to Dr Earl D. Bond, chief of clinical service and medical director of the Institute of the Pennsylvania Hospital, at a ceremony at the Academy of Music, February 8. The award, Philadelphia's highest civic honor, was founded twelve years ago by the late Edward W. Bok to be presented annually to the citizen who during the preceding calendar year has performed or brought to culmination an act or contributed a service calculated to advance the best and largest interests of the community of which Philadelphia is the center. Former Ambassador to Japan Roland S. Morris, chairman of the award committee made the presentation. Dr Bond has been head of the department for mental and nervous diseases at Pennsylvania Hospital since 1913, professor of psychiatry in the school of medicine since 1930 and in the graduate school since 1920. He is also director of the Philadelphia Child Guidance Clinic. He is the second physician to receive the Bok award the first having been Dr Chevalier Jackson in 1926. Dr Bond announced that he had arranged to turn the check accompanying the award into a fund for free treatment of mental patients in the institute.

SOUTH CAROLINA

Bill Introduced.—H 334 proposes to create a board of chiropods (podiatry) examiners and to regulate the practice of chiropods (podiatry). Chiropods (podiatry) as defined by this act is the surgical, medical and mechanical treatment of all ailments of the human foot.

SOUTH DAKOTA

Bill Introduced.—S 152 proposes to prohibit licensed physicians from collecting in the courts of the state for travel while attending a patient a greater sum than 25 cents for each mile actually traveled in attending the patient.

Bill Enacted—H 76, according to physicians, nurses and hospitals, caring for persons injured through the fault of other persons, liens on the claims, causes of action, judgments or settlements accruing to the injured persons on account of such injuries, has become a law

TEXAS

Bill Introduced—H 88 proposes to accord to hospitals or clinics, rendering hospital services, caring for persons injured through the fault of other persons, liens, limited to \$5 for each day of treatment, on any rights of action, recoveries or settlements accruing to the injured persons by reason of their injuries. This lien, however, is not to attach to claims or recoveries under the employer's liability act

UTAH

Bills Introduced—H 121 proposes to prohibit the dispensing or distribution of "chloral, paraldehyde, tinctura, opii, camphorata, sulphonethylmethanum, or any compound and derivative of barbituric acid" except on the prescription of a licensed physician. H 187, to amend the workmen's compensation act, in effect, proposes to permit chiropractors to render the medical aid required to be furnished to injured employees

VERMONT

Bill Introduced—H 173 proposes to create a board of naturopathic examiners and to regulate the practice of naturopathy. Licentiates are to be permitted to sign birth and death certificates

WASHINGTON

Bills Introduced—S 282 proposes that the nature of alcohol and other narcotics and their effects on the human system be included in the branches of study required to be taught in all public schools in the state. S 250, to amend the nursing practice act, proposes (1) to require all registered nurses to register annually and to pay an annual fee of \$1 and (2) to require all applicants for registration as registered nurses after March 1, 1936, to be graduates of accredited high schools and graduates of accredited training schools for nurses. S 266, to amend the workmen's compensation act, proposes, apparently, to make compensable all occupational diseases arising out of employments covered by the act. S 276, to amend the drugless therapeutics practice act, proposes that hereafter no separate certificates shall be issued to practice mechanotherapy, suggestive therapeutics, food science or physcultopathy, and that all licenses issued under the act be deemed licenses to practice naturopathy. Drugless therapeutics, the bill proposes, as defined by the act, is to be considered as synonymous with naturopathy

WISCONSIN

Bills Introduced—A 289, to amend the medical practice act, proposes to require applicants for licenses to practice medicine and surgery or osteopathy and surgery to be citizens of the United States. A 306 proposes to accord to hospitals treating persons injured through the fault of other persons liens on all causes of action, judgments, settlements or compromises accruing to the injured persons by reason of their injuries. A 370 proposes to prohibit the dispensing or other distribution of hypnotic drugs except on the prescription of a licensed physician, dentist or veterinarian. The bill defines hypnotic drugs to include diethyl barbituric acid, and other alkyl, aryl or metallic derivatives of barbituric acid, all urethanes and ureides, chloral hydrate or homologues thereof, sulphonal or derivatives thereof, and paraldehyde. S 207, to amend the medical practice act, proposes to reduce the board of medical examiners from eight to seven members and to repeal those provisions requiring the board to include three allopaths, two homeopaths, two eclectics and one osteopath. S 208, to amend the workmen's compensation act, proposes to authorize the industrial accident commission to order injured employees claiming compensation to be examined by a regular physician selected by the county medical society of that county in which the employee was injured. S 209, to amend the workmen's compensation act, proposes that the industrial accident commission shall have jurisdiction to pass on the reasonableness of medical and hospital bills when the county medical society or the hospital and the employer cannot agree

WYOMING

Bill Enacted—S 6, providing a penalty for any person practicing medicine, surgery or obstetrics without having first received and recorded a certificate from the state board of medical examiners, has been enacted as Chapter 24, Laws 1933

GENERAL

Medical Bills in Congress—*Changes in Status* H R 14395, relating to the prescribing of medicinal liquors, was passed by the House, February 25. It was amended so as to permit the prescribing of malt liquors. H R 14724, the Navy Department Appropriation bill, has passed the House. It carries a restricting clause which prohibits flight surgeons in the navy from receiving extra pay for flying

Report of Ella Sachs Plotz Foundation—Thirty-three grants for research in medicine and surgery were made during 1932 by the Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation. Eighteen were made to scientists in countries outside the United States. In accordance with the foundation's policy of giving aid to researches on a single problem or allied problems, seven of the investigations bear on nephritis, a subject that has received attention each year since the foundation was established nine years ago. Other general subjects favored are internal secretion and infection. Applications for grants for the year 1933-1934 should be in the hands of the executive committee before May 1. They should include statements as to the nature of the proposed research, the amount of money requested and the objects for which the money is to be expended. Dr Joseph C Aub, Collis P Huntington Memorial Hospital, 695 Huntington Avenue, Boston, is secretary of the committee

Vitamin Advisory Board Established—The establishment of the U S Pharmacopeial Vitamin Advisory Board for the preparation and distribution of vitamin standards within the United States, for scientific research only, has been announced. International vitamin standards for vitamins A, B and D, sent to this country by the Permanent Standard Commission of the Health Organization of the League of Nations, are to be issued without cost, but only for scientific research. It is anticipated that "Reference Cod Liver Oils" of known vitamin A or vitamin D potency will be distributed for the standardization of cod liver oil and other vitamin-active products. Members of the vitamin advisory board are

Lafayette B Mendel, Ph D, Yale University, New Haven
Henry C Sherman, Ph D, Columbia University, New York
Elmer M Nelson, Ph D, protein and nutrition division bureau of chemistry and soils, department of agriculture Washington D C
Evaander F Kelly, Baltimore, Pharm D, representing the U S Pharmacopeial board of trustees
E Fullerton Cook, Ph M, Philadelphia, representing the U S Pharmacopeial Commission Committee of Revision

Expenditures for Veterans—Authority to reduce by 5 per cent all benefits to veterans and other beneficiaries of the Veterans' Administration was requested by Brig Gen Frank T Hines, veterans' administrator, in a letter to the Senate subcommittee on appropriations, February 10. The letter was in answer to an inquiry from the committee concerning the effect of a 5 per cent cut in the appropriation for the coming year. General Hines pointed out that \$851,150,120 of the appropriation required for 1934 is not susceptible of reduction because certain items are specified in the organic law covering veterans' benefits. This would leave a remainder of \$115,688,514 to bear the reduction, which would amount to \$48,341,931.70, leaving only \$67,346,582.30 for administration, medical, hospital and domiciliary services and for hospital and domiciliary facilities. As hospitalization and domiciliary care alone will require about \$65,000,000, it is obvious that operation of these facilities would be seriously curtailed, General Hines said. He therefore asked for authority to cut all expenditures 5 per cent or to apply the 5 per cent cut only to the amounts not specified by law

CORRECTIONS

Catastatic—The word "catastatic" should have been omitted from the second sentence in the next to the last paragraph of the Query and Minor Note on "Predetermination of Sex by Controlling Reaction in Vagina," published in THE JOURNAL, February 18, page 519

Pasteur's Mistakes—The abstract entitled "Pasteur's Mistakes," which appeared in THE JOURNAL, February 18, page 516, seems to give the impression that the invectives against Pasteur were those of the author, Dr G B Webb, and not those of Robert Koch. Dr Webb writes asking THE JOURNAL to point out that the paragraph in his article preceding the abstract reads "Koch felt that Pasteur's Geneva address had been a polemic specifically attacking himself and his promised paper 'Über die Milzbrandimpfung' came 'red-hot from the grill'." Hear his invectives!

Manchester Rejects the Pasteurization of Milk

The authorities on public health teach that pasteurization of milk is a valuable measure for the prevention of the conveyance of tuberculosis and other diseases by milk and that, unless the milk can be absolutely guaranteed to be free from disease germs, milk should always be pasteurized. Yet the people of Manchester, one of the largest cities in England, have rejected pasteurization. The public health committee of the town council approved the proposal of the health officer that all milk other than tuberculin tested sold within the city should be pasteurized. The proposal was embodied in a bill for presentation to parliament, which was submitted to a town meeting. Opposition to the bill was so well organized that five of its clauses, including that for compulsory pasteurization, were defeated. The council, which approved of the bill by a large majority, then submitted the proposal to a poll of electors. Though the council issued 350,000 explanatory leaflets, the proposal was again defeated. It was pointed out in support of the bill that 75 per cent of the milk supplied to Manchester is pasteurized, that 323 children are infected every year with bovine tuberculosis from milk, that the treatment of this disease costs Manchester \$90,000 annually, that 40 per cent of the herds react to the tuberculin test, that 2 per cent of the milch cows have tuberculous udders, and that tubercle bacilli were found in 14 per cent of the milk supply. Against these powerful arguments it was alleged that pasteurization would drive the small milk producer retailers out of business and cost the farmers up to \$3,500 each for a pasteurization plant. The farmers said that what was needed was greater consumption of milk, that children prefer it raw, and that it is the small retailer who keeps the price down. Moreover, fresh milk is more nutritious, since pasteurization precipitates calcium and destroys vitamins. This is contrary to the pronouncement of the ministry of health that pasteurization properly performed ensures a milk which is not only safe but also retains its food value practically unimpaired. Propaganda was carried so far as the issue of posters and leaflets saying 'Pasteurization will kill your babies'. The result has well been described as a triumph of organized vested interests against good government.

The London Cancer Society

The London Cancer Society has recently been formed. It might be thought that the existence of so many medical societies in London and the comprehensive Royal Society of Medicine which has a section for every specialty, would render any further societies superfluous. It is true that there is no society specially devoted to cancer though there are two organizations devoted to cancer research but these are mainly concerned with experimental work. The new society will evidently be mainly clinical. The president is Mr Lockhart-Mummery, a pathologist. The objects of the society are to study every aspect of the cancer question and to report on new methods of diagnosis and treatment. An appeal is made to the profession to attend the meetings and bring forward any new idea or improvement in technique that may assist in curing or alleviating malignant disease. As regards diagnosis the view was expressed at the opening meeting that if the public would consent to periodic medical examination and if all methods of diagnosis were used few growths would escape detection at an early stage. On this idea the speaker threw cold water referring to cases in which the doctor failed to detect the beginning of a malignant growth and to the fact that by the time growths are

palpable or visible by the x-rays or the naked eye they may in certain regions be inoperable. Moreover, in the intervals between periodic examinations a quickly growing tumor may defeat the elaborate scheme. Another objection to the new society is that cancer is not a true specialty but a disease that comes within the province of every specialist. The true specialties are based on anatomic divisions of the body, on the basis of which is erected special knowledge of structure and function with corresponding special clinical knowledge and methods of diagnosis and technic in operating. All this has no application to a disease that can occur in any part of the body.

Death from Coronary Disease Held to Be an Accident of Employment

The extraordinarily wide manner in which the workmen's compensation act is applied in the courts has been pointed out in previous letters. Anything happening to a workman that can in any way be connected with his occupation is held to be an "accident arising out of and in the course of his employment" and therefore entitling him or his dependents to compensation. Contesting this by submitting that a man's death was not due to or connected with his work but to a fatal disease, from which he had long been suffering, has uniformly failed. The latest case shows that even death due to coronary disease can be held to be an "accident" arising out of employment. A man employed in the process of dipping heavy sheets of metal into a pot of dross and removing them had to clean out the dross from the pot after dipping a certain number. After he had finished cleaning he exclaimed "O my chest" and died within ten minutes. The case came into court. The medical evidence was that he had been suffering from disease of the coronary arteries for some time but that the physical exertion that he underwent in performing his ordinary work accelerated his death. The judge decided that the death was caused by accident "arising out of and in the course of the man's employment" within the meaning of the workmen's compensation act and awarded \$3,000 compensation to his widow and children. An appeal was made and the higher court confirmed this judgment. A further appeal was now made to the highest court in this country the House of Lords. In giving judgment Lord Buckmaster said that the case that was made against the judgment appealed from was that, in order to show that a man was entitled to the benefit of the act, it was necessary to show that he had suffered an injury as the result of some definite thing that he did in the course of his work. If in the normal course of his activities, owing to the imperfect condition of his arteries, he broke down and died, the appellant's case was that that was not sufficient unless one could point to a specific injury resulting from a specific act. Whatever might be said about the merits of that argument some twenty years ago it was impossible to be advanced today while that house as well as inferior courts was bound by what was done in a previous case of the kind. In it the judge had held that the result of work was failure of blood supply resulting in angina pectoris and that it was because the man was engaged in doing his ordinary work in that disease condition that the work and the disease together contributed to his death. In the present case the five judges of the House of Lords agreed in confirming the judgment of the lower court.

The Coming Flight Over Mount Everest

Another attempt is to be made to climb the highest mountain in the world Mount Everest (29,141 feet), accompanied by flight over the summit by two airplanes. Elaborate preparations have been made for the flight. Oxygen and heating electrical apparatus have been provided. The main supply of oxygen will be carried in three 750-liter cylinders which should afford a sufficient supply for the two occupants of the machine for a period of two and one half hours even if the machine

taken from cadavers whose death occurred more than twelve hours before the blood is collected may cause grave poisoning, its use is not advisable. The method is indicated in all the cases in which transfusion is indicated. After a Wassermann test and the determination of the blood group, the blood is kept in the icebox until a transfusion is necessary. In this way, a man may be useful to his fellow men even after death.

Spain Needs More Hospitals and Asylums

Dr B. Hernúnda recently published an article in which he expresses the necessity for more hospitals and insane asylums in Spain. The Asylum of Pilar de Saragossa has 700 patients, most of them from the provinces of Aragon. The insane asylum of Leganes has 400 psychiatric patients. The list of psychiatric patients waiting to be admitted to the asylum is enormous. Fifty-five names are on the waiting list of the insane asylum of Leganes. In the asylum of Carmen for incurable patients there are 254 patients, and 370 on the waiting list. The asylum of Jesus Nazareno for women has 242 beds and a waiting list of 876. Similar figures could be obtained from all the rest of the asylums in Spain.

Physicians Honored

Dr. Madrazo of Santander was the first surgeon who practiced antiseptic surgery in Spain. Dr. Madrazo's life has been spent in doing good to his fellow countrymen, by whom he is greatly loved. However, months ago, some unknown person placed a bomb in Dr. Madrazo's home, the explosion of which damaged the building. The people of the province were indignant and recently manifested their esteem for Dr. Madrazo by unveiling a monument to him at the entrance to a school which Dr. Madrazo gave twenty-five years ago to the city for the education of children. Dr. Madrazo is 85 years old.

Dr. Ayela of Ijona, Alicante, was recently honored by his countrymen, who unveiled a monument to him. Dr. Ayela has devoted his life to doing good for others.

Dr. Marañón's beautiful residence at Toledo was once the residence of Tirso de Molina, who wrote Don Juan. At Dr. Marañón's house the document recognizing the republic was signed by representatives of the falling monarchy. Recently Dr. Marañón gave a banquet to members of the cabinet, the ministers of France and of Spain, and other diplomats. Later Dr. Marañón went to Paris, where the University of Paris conferred on him the title of Doctor Honoris Causa, because of his scientific studies. At the Sorbonne, Dr. Balthazard presented the emblems of the University of Paris and made reference to the scientific work of Marañón. Dr. Marañón aided his country in giving a better government without bloodshed and then declined any honors from the republic, that he might continue to practice medicine.

Accidental Thallium Poisoning of Children

In a previous letter was reported an accident in an orphan asylum in Granada, where thallium salts were prescribed for the treatment of ringworm in children, and through a mistake of the physician the children were given a dose ten times larger than the average dose. As a result, fourteen children died. The judge found Dr. C. Puertas Gaona guilty of the death of the children and Dr. I. Duran, the pharmacist J. Muñoz Medina, and the intern J. Calero Lopez guilty as accomplices. The defendants did not ask for judicial aid. Dr. Gaona was given two years, four months and one day in prison. Duran, Medina, and Lopez will pay a fine of 500 pesetas (\$50) and the costs of the case.

Deaths

Dr. Pulido Fernandez, retired secretary of the National Academy of Medicine of Madrid and of the Senate, died in Madrid at the age of 82. He had been director of the Anatomical

Museum of Madrid, founder of several medical and scientific journals, and author of books of medicine, surgery and public hygiene. He was a great orator, and a vice president and life member of the Senate. Through his efforts, the first clinics of specialists were opened in Spain, and the situation among mental patients was improved. He convinced the judges that frequently mental disease is the underlying condition in conflicts between individuals and the penal code. Capital punishment in Spain previously took place in public, Dr. Pulido Fernandez asked that the law be modified. Capital punishment takes place now inside the prisons. Dr. Pulido Fernandez taught anatomy, surgery, gynecology and other subjects in the medical curriculum. He devoted most of his life to the development of social medicine. He was representative of Spain at the Office international d'hygiene in Paris for several years. While he was director of public health in Spain he wrote a book on sanitation and sewerage, with especial reference to conditions prevailing in Sevilla, which have since been changed. He organized several campaigns against bubonic plague in Portugal and the Canary Islands. He was a great speaker, but on one occasion he had an emotional inhibition of the voice, and he wrote a book on this topic, called "La Emocion Oratoria," which has been published in several languages.

Dr. Mejias Is Dead

Dr. J. Mejias, director of the Instituto de Terapeutica Biologica of Dr. Llorente, is dead. He was the first Spanish physician to go around the world in an airplane, the *Conde Zepelin*. He made the same trip several times. He wrote a book on aviation. He often said that a physician in an airplane is necessary to those persons in whom disturbances of the circulatory system due to high altitudes occur.

Marriages

HEWITT HASSAILE ROBINSON, Meridian, Miss., to Miss Jeanette Hamilton of Oakland, Calif., at Stanford University, Calif., January 1.

ELIAS SAMPSON FAISON, Faison, N. C., to Miss Gloria Jones of Little Rock, Ark., in Vienna, Austria, Dec. 17, 1932.

WILLIAM S. HATHAWAY, Rochester, Mich., to Miss Joan Elizabeth Mitchell of Sarnia, Ont., Canada, January 14.

JAMES ALEXANDER WHITE, Alexandria, La., to Mrs. Josephine Moore Bethune at Augusta, Ga., January 25.

HAROLD B. HOGUE, Ewen, Mich., to Miss Marjory Roberts of Los Angeles, at Elmhurst, Ill., Dec. 31, 1932.

TADEUSZ MARYAN LARKOWSKI to Florentina Malachowski, DDS, both of Chicago, January 25.

JOHN L. HAMILTON, Barnesboro, Pa., to Miss Helen Wells of Steubenville, Ohio, Dec. 17, 1932.

GEORGE W. WALBRIGHT, Metropolis, Ill., to Miss Dora E. Thacker of Danville, Dec. 25, 1932.

OLIVER COPE, Philadelphia, to Miss Alice De Normandie of Lincoln, Mass., Dec. 28, 1932.

EDWIN O. VAUGHAN to Miss Louise Cunningham, both of St. Albans, W. Va., February 9.

CECIL HOLMES RAND, Fremont, N. C., to Miss Lucile Slade at Boydton, Va., January 14.

EDMOND FRANCIS LEX, Tiffin, Ohio, to Miss Veronica Grilhot of Versailles, January 5.

GEORGE R. SEWARD, Peoria, Ill., to Miss Grace Rosenbaum of Bradford, January 23.

EUGENE FALSTEIN to Miss Charlotte Rosenfield, both of Chicago, Dec. 25, 1932.

JACOB D. FLEMING, Frazeyburg, Ohio, to Miss Ella Shiplev, January 23.

SAMUEL A. SCUDERI, Los Angeles, to Miss Leah Ciocca, Dec. 3, 1932.

GRANT E. ROYCE, Harvard, Ill., to Miss Charlotte Wakeley, January 11.

Deaths

Albert Vincent Hennessy ♂ Council Bluffs, Iowa, State University of Iowa College of Medicine, Iowa City, 1906, associate professor of clinical surgery, Creighton University School of Medicine, Omaha, served during the World War, on the staffs of the Mercy Hospital and St. Bernard's Hospital, aged 48, was killed, January 15, when he fell or jumped from a window of his room on the sixteenth floor of a hotel in New York.

Erwin Bertrand Herrington, Findlay, Ohio, University of the City of New York Medical Department, 1889, University of Louisville (Ky.) School of Medicine and the Louisville (Ky.) Medical College, 1896, member of the Ohio State Medical Association, aged 67, died January 12, in the Robinwood Hospital, Toledo, of abscess of the hip as the result of a fall.

Kirkland Ruffin, Norfolk, Va., University of Virginia Department of Medicine, Charlottesville, 1886, member of the Medical Society of Virginia, fellow of the American College of Surgeons, formerly on the staffs of Norfolk Protestant Hospital, Hospital of St. Vincent de Paul and St. Christopher's Hospital, aged 66, died, Dec. 25, 1932.

Robert Edgar Baldwin ♂ Tampa, Fla., University of Louisville (Ky.) School of Medicine, 1909, member of the Radiological Society of North America, served during the World War, superintendent of the Tampa Hospital, aged 46, died, February 2, at the Mayo Clinic, Rochester, Minn., of duodenal ulcer, nephritis and uremia.

William McDowell Mastin, Mobile, Ala., University of Pennsylvania School of Medicine, Philadelphia, 1874, member of the American Surgical Association and the Southern Surgical Association, fellow of the American College of Surgeons, surgeon to the Providence Infirmary, aged 79, died, February 3, of pneumonia.

Richard Blackmore, Northport, N. Y., Boston University School of Medicine, 1902, member of the American Psychiatric Association and the New England Society of Psychiatry, served during the World War, aged 60, on the staff of the Veterans' Administration Hospital, where he died, February 6, of heart disease.

Van Horne Norrie ♂ New York, College of Physicians and Surgeons in the City of New York, Medical Department of Columbia College, 1889, professor of clinical medicine at his alma mater, director of the medical service and visiting physician to the Bellevue Hospital, aged 70, died, January 31, of heart disease.

Dean Tyler Smith, Holly Hill, Fla., Chicago Homeopathic Medical College, 1889, fellow of the American College of Surgeons, at one time professor of surgery and clinical surgery, University of Michigan Homeopathic Medical School, Ann Arbor, aged 72, died, January 29.

Edward M. Irwin, Belleville, Ill., Missouri Medical College St. Louis, 1892, member of the Illinois State Medical Society, for twenty-five years bank president, formerly congressman and coroner, aged 63, died, January 30, in St. Elizabeth's Hospital, of pneumonia.

David Caneen Northcross, Detroit, College of Physicians and Surgeons of Chicago School of Medicine of the University of Illinois, 1906, aged 56, died, January 3, in the Receiving Hospital, of stab wounds inflicted by a tenant from whom he endeavored to collect rent.

Duncan Brown McEachern ♂ Chicago, Jenner Medical College, Chicago, 1906, College of Physicians and Surgeons of Chicago School of Medicine of the University of Illinois, 1907, on the staff of the Southshore Hospital, aged 56, died, February 6, of heart disease.

Frederick Karl Kislig ♂ Dayton, Ohio, Starling-Ohio Medical College, Columbus, 1911, fellow of the American College of Surgeons, served during the World War, aged 45, urologist to the Miami Valley Hospital, where he died, February 7, of heart disease.

John Cook, Douglas, Ariz., Baltimore Medical College, 1902, member of the Arizona State Medical Association, fellow of the American College of Surgeons, served during the World War, aged 60, died January 12 in Portal, of carcinoma of the intestine.

James Bowdon Bird ♂ Kansas City, Mo., Washington University School of Medicine St. Louis, 1906, aged 51, on the staff of St. Joseph Hospital, where he died January 27, when the automobile in which he was driving was struck by a street car.

Ronald Steele Saddington, New York, University of Toronto Faculty of Medicine, Toronto, Ont., Canada, 1927, on the staff of the Rockefeller Institute for Medical Research, aged 30, died, February 4, of pulmonary embolism and thrombophlebitis.

Thomas Joseph Crowley, San Mateo, Calif., University of California Medical Department, San Francisco, 1898, member of the California Medical Association, aged 63, died, Dec. 23, 1932, of bronchopneumonia and influenza.

Robinson C. Dorr, Batesville, Ark., Missouri Medical College, St. Louis, 1883, member of the Arkansas Medical Society, fellow of the American College of Surgeons, formerly bank president, aged 74, died, January 29, of senility.

Yancey N. New, Danville, Ind., Kentucky School of Medicine, Louisville, 1893, member of the Indiana State Medical Association, aged 64, died, Dec. 20, 1932, in the Methodist Hospital, Indianapolis, of cerebral hemorrhage.

Albion Sullivan Marden, Newport, N. H., Dartmouth Medical School, Hanover, 1883, member of the New Hampshire Medical Society, aged 80, died, Dec. 6, 1932, in New Brunswick, N. J., of lobar pneumonia.

Benjamin Oscar Barber, Pownal, Vt., Cleveland Medical College, 1877, formerly superintendent of the town schools, school director, member of the board of health, and justice of the peace, aged 84, died, January 13.

Wesley Pitt Wells, Zanesville, Ohio, Medical College of Ohio, Cincinnati, 1877, also a druggist, at one time member of the city council and school board, aged 77, died suddenly, January 1, of cerebral hemorrhage.

Julian Carman Kennedy, San Francisco, University of Colorado School of Medicine, Denver, 1911, aged 47, died, Dec. 17, 1932, of cirrhosis of the liver, bronchopneumonia and thrombosis of the coronary artery.

Daniel L. McSwain ♂ Arcadia, Fla., Tulane University of Louisiana Medical Department, New Orleans, 1899, on the staff of the Arcadia General Hospital, aged 62, died, January 28, of coronary thrombosis.

Fisher Randall Clarke, Stockton, Calif., Kentucky School of Medicine, Louisville, 1891, member of the California Medical Association, aged 86, died, Dec. 12, 1932, of myocarditis and hypertrophy of the prostate.

Romeo E. Hyde, Plattsburg, N. Y., Albany (N. Y.) Medical College, 1868, Civil War veteran, formerly mayor of Plattsburg, aged 89, died, February 1, in the Physicians' Hospital, of bronchopneumonia.

Merton Price ♂ San Francisco, Stanford University School of Medicine, San Francisco, 1916, member of the Pacific Coast Oto-Ophthalmological Society, aged 44, died, Dec. 23, 1932, of influenza and lobar pneumonia.

Ibnsina Charles Anker, Modesto, Calif., Hahnemann Hospital College of San Francisco, 1892, College of Physicians and Surgeons, Chicago, 1894, aged 76, died, Dec. 14, 1932, of chronic myocarditis.

Ernst Ferdinand Foerster, Brooklyn, University of the City of New York Medical Department, 1894, member of the Medical Society of the State of New York, aged 64, died in February of heart disease.

Andrew Shuttleworth Reisor, Shreveport, La., Tulane University of Louisiana Medical Department, New Orleans, 1907, member of the Louisiana State Medical Society, aged 49, died, Dec. 9, 1932.

John E. Brennan ♂ New Milford, Conn., Georgetown University School of Medicine, Washington, D. C., 1905, on the staff of the New Milford Hospital, aged 52, died, February 9, of heart disease.

John Howard Nesbitt ♂ Dallas, Texas, Baltimore Medical College, 1905, served during the World War, connected with the Veterans' Administration, aged 52, died in December, 1932, of heart disease.

Malcolm Cameron, Retsil, Wash., Hahnemann Medical College of Philadelphia, 1881, Civil War veteran, aged 87, died Dec. 22, 1932, in the United States Naval Hospital, Bremerton.

Nelson D. Haskell, Buffalo, Cleveland College of Physicians and Surgeons, Medical Department of the University of Wooster, 1891, aged 82, died, January 23, of carcinoma of the prostate.

Adolph Hirschfield, Minneapolis, University of Minnesota Medical School, Minneapolis, 1893, member of the Minnesota State Medical Association, aged 68, died January 3, of heart disease.

Percy Bradford Lusk, New Orleans, Tulane University of Louisiana Medical Department, New Orleans, 1884, aged 72, died, January 25, of cerebral hemorrhage and edema of the lungs

William H Weaver, Canton, Ohio, Ohio Medical University Columbus, 1902, aged 58, on the staff of the Mercy Hospital, where he died, January 28, of carcinoma of the rectum

Louis d'Orville Chabut, Youngstown, Ohio, Jefferson Medical College of Philadelphia, 1890, veteran of the Spanish-American War, aged 76, died, Dec 4, 1932, in Jackson, Mich

Albert Matthias Freund, Cincinnati, State University of Iowa College of Medicine Iowa City 1888, aged 71, died, January 18, in St Francis Hospital, of auricular fibrillation

William Moller Schroeder, Newark, N J, University of Vermont College of Medicine Burlington, 1902, aged 54, died, Dec 13, 1932, in New Canaan, Conn, of angina pectoris

Harry Rolland Adams Ⓢ Onsted, Mich, College of Physicians and Surgeons, Keokuk, Iowa 1893, aged 65, died, January 26 in the Baby Hospital, Adrian, of heart disease

Joseph Dixon, Greenville, N C, Medical College of Virginia, Richmond, 1894, aged 68, died, January 21, in the Tucker Sanatorium Richmond, Va, of cerebral arteriosclerosis

Albert Ciegler Armitage, Hagler, Neb, Keokuk (Iowa) Medical College, 1891, member of the Nebraska State Medical Association, aged 69, died, January 3, of pneumonia

Joseph W Moffett, Oklahoma City, University of Texas School of Medicine, Galveston, 1898, aged 64, died, Dec 5, 1932, in St Anthony Hospital, of bronchopneumonia

Joseph Sherlaw, Chicago, Long Island College Hospital, Brooklyn, 1895 member of the Illinois State Medical Society, aged 72, died, February 13, of cerebral hemorrhage

Smith Davis Taylor, Gary, Ind, Louisville (Ky) Medical College, 1903, member of the Indiana State Medical Association, deputy coroner, aged 54, died, Dec 31, 1932

Julian Theodore Field, Fort Worth, Texas, University of Louisville (Ky) School of Medicine 1869, Confederate veteran, aged 86, died, Dec 25, 1932, of pneumonia

John N Quillin, Villa Grove Ill, College of Physicians and Surgeons, Keokuk, Iowa, 1884, aged 81, died, January 7, in Mount Vernon, Ohio, of cerebral hemorrhage

Ben L Bruner, Louisville, Ky, Hospital College of Medicine, Louisville, 1897, formerly bank president, at one time secretary of state, aged 60, died, Dec 15, 1932

John S Sennott, Waterloo, Ill, St Louis Medical College, 1883, member of the Illinois State Medical Society, aged 71, died, January 3, of bronchopneumonia

John U Hobach, Lancaster, Pa, University of Pennsylvania School of Medicine, Philadelphia, 1884, aged 77, died, February 1, of carcinoma of the stomach

Halbert Fletcher Neal, Meridian, Idaho, University of Nebraska College of Medicine, Omaha, 1903, aged 53, died suddenly, January 31, of angina pectoris

Herman Ellsworth Meeker, New York, Bellevue Hospital Medical College, New York, 1896, aged 66, died, January 14, of pneumonia and myocarditis

William Joseph Cooney, New Haven Conn, Yale University School of Medicine, New Haven, 1902, aged 57, died, January 22, of pulmonary tuberculosis

Thomas William Griffin, Woodstock, N B, Canada, Jefferson Medical College of Philadelphia, 1898, aged 58, died suddenly, February 6, of heart disease

William Harvey Hardin, Calhoun City, Miss, University of Tennessee Medical Department, Nashville, 1894, aged 81, died, January 20, of chronic nephritis

Hiram Craig Shouse, Plankinton, S D, Hahnemann Medical College and Hospital, Chicago, 1872, Civil War Veteran, aged 88, died, January 16, of uremia

Irwin Arthur O'Connor, St Paul, University of Minnesota Medical School, Minneapolis, 1923, aged 34, died, Dec 25 1932, of influenza and pneumonia

Jacob Benjamin Baruch, Jr, Detroit, Michigan College of Medicine and Surgery, Detroit, 1903, aged 72, died, January 2, of uremia and prostatic obstruction

Martin Dowling, Zeist, Netherlands, University of the City of New York Medical Department, 1895, aged 60, died suddenly, January 14, of heart disease

Lucien Winslow Gordon, Equality, Ill, Miami Medical College, Cincinnati, 1880, aged 74, died, January 8, of paralysis agitans and capillary bronchitis

Louis Henry Kraus, New York, New York Homeopathic Medical College and Flower Hospital, New York, 1915, aged 67, died, Dec 22, 1932

Daniel Webster Palmer, Cape Charles, Va, Leonard Medical School, Raleigh, N C, 1904, aged 55, died, Nov 10, 1932, of cerebral hemorrhage

Enoch Merrill Miller, Glendale, Calif, Kansas City (Mo) Hahnemann Medical College, 1903, aged 53, died, Dec 27, 1932, of chronic myocarditis

Frederick Arnold Brandt, Sturgis, S D, Washington University School of Medicine, St Louis, 1904, aged 51, died, in January, of heart disease

James Valarus Bonnette, Alexandria, La, Kentucky School of Medicine, Louisville, 1893, aged 67, died, January 25, of cerebral hemorrhage

John Crawford, Santa Paula, Calif, Columbus (Ohio) Medical College, 1887, aged 72, died, Dec 15, 1932, of acute cholecystitis and peritonitis

William John Shields, New York, Long Island College Hospital, Brooklyn, 1897, died, January 18, in a hospital at Sarasota, Fla, of nephritis

Henry F Askam, Atlanta, Ga, University of Louisville (Ky) School of Medicine, 1880, aged 78, died suddenly, January 19, of angina pectoris

Herbert P Morrey, Santa Barbara, Calif, Keokuk (Iowa) Medical College, 1893, aged 72, died, Dec 12, 1932, of arteriosclerosis and hypertension

Henry R Ressel, South Haven, Mich, Medizinische Fakultät der Universität Wien, Austria, 1892, aged 67, died, January 22, of heart disease

Frederick Augustus McClain, Bessemer, Ala, Louisville (Ky) Medical College, 1894, aged 60, died, January 8, of carcinoma of the esophagus

Susan Dew Hoff, West Milford, W Va (licensed, in West Virginia, under the Act of 1889), aged 90, died, January 2, of cerebral hemorrhage

George Alonzo Mershon Ⓢ Marshalltown, Iowa, Physio-Medical Institute, Cincinnati, 1882, aged 80, died, Dec 20, 1932, of chronic colitis

William Preston McGlenn, Louisville, Ky, Hospital College of Medicine, Louisville, 1878, aged 76, died, January 22, of aortic regurgitation

William S Richardson Ⓢ Williamsport, Md, College of Physicians and Surgeons, Baltimore, 1890, aged 76, died, Dec 29, 1932, of influenza

George Smieding, Tampa, Fla, Rush Medical College, Chicago, 1900, aged 56, was found dead, January 26, of a self-inflicted bullet wound

John D Nuchols, Benton, Tenn, Tennessee Medical College, Knoxville, 1891, aged 64, died, Dec 31, 1932, of pneumonia and paralysis

Rensselaer Jewett Smith, Milpitas, Calif, University of the City of New York Medical Department, 1884, aged 74, died, Dec 13, 1932

Charles W McCollum, Bullsgap, Tenn, Louisville (Ky) Medical College 1892, aged 68, died, Dec 7, 1932, in a hospital at Greenville

Homer Lee Kulenwider, Los Angeles, Medical College of Indiana, Indianapolis, 1904, aged 61, died, Dec 7, 1932, of pulmonary edema

Martin Gonzalez, Laredo, Texas, Escuela de Medicina de Nuevo Leon, Monterrey, Mexico, 1877, aged 82, died, Dec 23, 1932, of influenza

Charles Egan, Highland, Wis, Rush Medical College, Chicago, 1875, aged 84, died, January 23, of chronic myocarditis

John T Murray Ⓢ Manchester, N H, Baltimore University School of Medicine, 1898, aged 64, died, Dec 16, 1932

Benjamin D Brown Ⓢ Apache, Okla, Hospital College of Medicine, Louisville, Ky, 1898, aged 62, died, Dec 25, 1932

Julius B Manley, North Los Angeles, Calif, Eclectic Medical Institute, Cincinnati, 1889, aged 75, died, Dec 2, 1932

Lewis E Haskins, Alaska, Mich (licensed, in Michigan by years of practice), aged 87, died, January 25, of senility

George V Hilton, Lowell, Mass, Detroit Medical College, 1876, aged 81, died, January 13, of bronchopneumonia

Edmond J Bowles, Chicago, Chicago Medical School, 1923, aged 53, died, February 7, of acute myocarditis

Joseph E Baynes, Troy, N Y Albany (N Y) Medical College, 1886, aged 68, died, Dec 21, 1932

Correspondence

USE OF INHALATIONS OF CARBON DIOXIDE TO PREVENT POSTOPERATIVE PUL- MONARY COMPLICATIONS

To the Editor—Less than five years ago Coryllos and Birnbaum, on the basis chiefly of experimental observations, announced the exceedingly important and illuminating doctrine that obstruction of the bronchi is the condition that commonly induces postoperative pulmonary complications. From clinical observations at about the same time Scott and Cutler reported that hyperventilation with carbon dioxide after operations, as recommended by Henderson, Haggard and Coburn, greatly diminishes pulmonary complications. It is this and other clinical demonstrations of the fact that clearing the bronchi tends to prevent subsequent complications which establishes the critical importance of bronchial obstruction. Without this therapeutic or prophylactic benefit, that doctrine would be merely a brilliant hypothesis.

There appears to be at present a general acceptance of this doctrine, combined illogically with a failure to realize that doctrine and evidence stand or fall together. This confusion is shown in a paper in *THE JOURNAL*, January 7, from the Massachusetts General Hospital, by Dr D S King.

Dr King starts out in his paper to test the efficiency of carbon dioxide as a preventive of postoperative pulmonary complications. In his first series of observations during four months, the number of complications in the treated cases was far below that for the untreated cases. It then occurred to him that, as the purpose of carbon dioxide inhalation is to clear the bronchi and inflate the lungs, perhaps the production of bronchial drainage by frequent change of posture would also be effective. From then on for several months all of the so-called control subjects were given the benefit of postural change. The result was that the treated cases and the untreated controls showed nearly similar results. Although no amount of study has been able to explain away the first and only well controlled series of cases, the practical conclusion, based apparently on the second series, is that "In the Massachusetts General Hospital, therefore the routine use of carbon dioxide as a preventive measure against postoperative pulmonary complications has been discontinued and the search for a more effective method is still being pursued." Whether the equally effective or ineffective method of postural change has also been discontinued is not stated. Support is however expressed for the view that immediate postoperative deetherization with carbon dioxide may cause a deeper inhalation of bronchial secretion and so perhaps do harm—a conception offered wholly without evidence and contrary to practically the entire weight of the experience of all competent anesthetists.

Obviously the evidence from the second series of cases controlled by other cases in which bronchial drainage was promoted by frequent postural changes proves little or nothing regarding the ostensible object of the investigation. The underlying assumption involved in the discussion is however of great importance. It is that obstruction of the bronchi is the common cause of postoperative pulmonary complications. This doctrine is evidently assumed to be so well established and so obvious as to be sufficiently tested by comparison of two procedures both of which are based on this doctrine. Yet Dr King, on the basis of his tests, rejects one of these procedures and does not indicate that the other is any better.

It is certainly to be hoped that Dr King succeeds in his pursuit of a more effective method of applying this doctrine than either of those now available. But as that pursuit may perhaps take him some time, why reject such means as are

now available and such as Dr King's own observations in his first series of experiments show to be effective, for clearing the bronchi, inflating the lungs, inducing drainage and preventing postoperative pulmonary complications?

It is at least evidence of the enormous progress during the past five years in this field, in which there was formerly a considerable mortality, that surgeons now face responsibility for the postoperative period—a responsibility that was quite ineffective so long as such developments as postoperative pulmonary complications were entirely obscure and their outcome therefore wholly "in the hands of God."

YANDELL HENDERSON, PH D, New Haven, Conn

[A copy of Dr Henderson's communication was sent to Dr King, who replies.]

To the Editor—In reply to Dr Yandell Henderson's comment on my paper on the use of carbon dioxide as a preventive of postoperative pulmonary complications, I should like to restate my position as follows.

1 I have no desire to minimize the importance of adequate postoperative bronchial drainage. I believe that the concept of bronchial obstruction and atelectasis answers many, though by no means all, of the questions arising in connection with postoperative pulmonary complications.

2 I conclude from my series that bronchial drainage by either postural change or carbon dioxide inhalation prevents a certain proportion of complications, and that one method is no more effective than the other, but that since postural change is easier and less expensive it is the method of choice. It is still being used at the Massachusetts General Hospital.

3 So far as the use of carbon dioxide is concerned, I disagree with Dr Henderson as to what constitutes clinical evidence of its value. In my paper I analyzed all the articles quoted by him as proving its usefulness. In my opinion, none of these authors present satisfactory evidence in the form of an adequately controlled series.

4 Dr Henderson fails to note that the point that "no amount of study has been able to explain" is the record for one month only, February, and if it were not for this one month there would be little evidence in my series of the value of carbon dioxide, even when the controls were not having postural change. The month of February was also one in which the treated group received very little hyperventilation.

5 As to the use of carbon dioxide for deetherization in the operating room, it should be noted that we had used this method for seven months previous to the study under discussion. During this period, pulmonary complications developed in 13.1 per cent of the laparotomies and herniorrhaphies, a higher figure than we had ever recorded before. We therefore had a right to fear that this procedure might be doing harm.

DONALD S KING, M D, Boston

ETIOLOGY OF WHOOPING COUGH

To the Editor—The present communication was inspired by the appearance in your editorial columns during the past six weeks of two comments on the etiology of whooping cough (*THE JOURNAL*, Nov. 26, 1932, p. 1866 and Dec. 17, p. 2115). Most of our knowledge of the bacteriology and serology of whooping cough has come from Europe, yet in your columns, widely read in Europe, such foreign data are not mentioned.

Thorvald Madsen (*Boston M & S J* 192:50 [Jan. 8] 1924) summarized the work of his staff at the Danish National Serum Institute in the Cutler Lecture given at Harvard University Medical School in 1924. He described the results obtained with the "cough plate" of Chievitz and Meyer (*Ann de l'Inst Pasteur* 30:503 [Oct.] 1916), which has now been used for sixteen years as a routine diagnostic procedure in Denmark.

The acceptance of this procedure by the Danish medical profession is based on three facts

1 The close association of the Bordet-Gengou bacillus with cases of whooping cough (The best Danish figures of 88 per cent are exceeded by those of Sauer and Hambrecht [*THE JOURNAL*, July 26, 1930, p 263], who obtained 98 per cent positive plates in the catarrhal stage)

2 The absence of the organism in the cough droplets of 1,000 healthy children and adults who were not in contact with cases of pertussis (Kristensen, Bjørn Thesis "Om Forekomsten af Bordet-Gengou's Bacil," from Statens Seruminstitut, Copenhagen, 1932)

3 The great frequency with which the organism is isolated in the catarrhal stage the time observed to be most contagious, and the subsequent diminishing frequency which parallels the observed degree of communicability

The Danish medical profession has also accepted as an occasionally useful procedure the complement fixation test with the Bordet-Gengou antigen. Because of this late appearance of the complement fixing antibodies, the test is obviously resorted to only in cases of atypical chronic coughs

Probably the most encouraging results obtained with vaccines of the Bordet-Gengou bacillus are those recorded by Madsen in Copenhagen and in the Faroe Islands. During the past few years further data have been collected in Denmark on the effect of vaccine in preventing or modifying an attack of the disease. This material has not yet been published but with Dr Madsen's consent I may report that the results obtained are comparable with the Faroe Islands success. I am well aware that such experiences have not been duplicated often and that pertussis vaccines have been removed from New and Nonofficial Remedies. It is logical to suppose that the wide diversity of the results obtained with this agent is in a measure dependent on the diversity of the mode of preparation. Leslie and Gardner (*J Hyg* 31 423 [July] 1931) have presented evidence that the Bordet-Gengou bacillus passes rather rapidly through a series of antigenically distinct phases when grown on artificial mediums. They found that recently isolated strains in "phase I" were alone reliable for the production of active immunity in guinea-pigs. The Danish vaccine has always been prepared from strains less than three weeks old. It is obvious that a vaccine containing from ten to twenty such strains can be prepared only in a laboratory in which new strains are received daily, namely, in a "cough plate" diagnostic station.

In addition to their contributions on the antigenic phases of the organism in question, Gardner and Leslie (*Lancet* 1 9 [Jan 2] 1932) reviewed the entire subject one year ago. These Oxford bacteriologists conclude "There is no longer any room for doubt that the bacillus of Bordet and Gengou is the true and sole cause of whooping cough." Certainly not all investigators feel quite so positive. Those who have read the report of Brown (*Bull Johns Hopkins Hosp* 38 147 [Feb] 1926) in which is described a case simulating pertussis from which *Brucella bronchiseptica* (and not *Haemophilus pertussis*) was isolated might qualify this pronouncement by substituting "the common cause" for "the true and sole cause." McCordock's (*Proc Soc Exper Biol & Med* 29 1288 [June] 1932) recent observation of intracellular inclusion bodies in the lungs of patients with pertussis is stimulating. Whatever their explanation may eventually prove to be, it must be accompanied by an explanation of the association of *H. pertussis* with the disease. The recent investigations of Rich, Long, Brown, Bliss and Holt (*Science* 76 330 [Oct 4] 1932) appear to confirm the older work of Frankel (*Munchen med Wchschr* 55 168, 1908), Inaba (*Ztschr f Kinderh* 4 252, 1912) and Sauer and Hambrecht (*Am J Dis Child* 37 732 [April] 1929). These earlier investigators produced a syndrome simulating whooping cough in monkeys by the administrations of Bordet-Gengou bacilli.

In the light of these references to foreign work and foreign views, the leading sentence of your second editorial is inadequate

The editorial said "The current assumption that whooping cough is caused by the Bordet-Gengou bacillus and that prophylactic immunization with the corresponding Bordet-Gengou vaccine is justifiable is based solely on clinical impressions." I affirm that the assumption of the etiologic role of the Bordet-Gengou bacillus is based on far more than clinical impression. The examinations of thousands of cough plates and hundreds of serums from children with and without whooping cough over a period of sixteen years does not yield "clinical impression" but rather facts which would convict the Bordet-Gengou bacillus on circumstantial evidence in a court of law, if not in a court of medicine.

SODIUM THIOCYANATE (RHODANATE) AND THE THEORY OF AGGLOMERATION

To the Editor—A timely editorial comment in *THE JOURNAL*, Dec 31, 1932, page 2270, calls attention to the extraordinary advertising and clinical activities of Prof Wilder D Bancroft of Cornell University. It is unfortunate that the comment did not go on to indicate the equally extraordinary character of Professor Bancroft's alleged scientific investigations into the colloid chemistry of anesthesia, disinfection, sleep, the central nervous system, insanity, drug addiction, and many other difficult medical propositions—such as anaphylaxis and strychnine poisoning. These publications by Professor Bancroft and his pupils have appeared since 1930 in the *Proceedings of the National Academy of Science* (of which Professor Bancroft has long been a member) and the *Journal of Physical Chemistry* (which Professor Bancroft founded and edited), and of course they have been prominently featured by the public press. Perusal of these many papers reveals a number of remarkable features common to them all: (1) an astonishing ability to argue a priori in support of a preconceived idea, (2) a regrettable paucity of adequate experimental data to support the voluminous "conclusions" drawn, and (3) an interesting selection of statements taken from biologic literature to help the argument. Average second year medical students on whom I made the test could see how ridiculous, though plausible, an able physical chemist may become when he ventures to indulge in interesting speculations in a biologic field in which he has had inadequate training and experience.

There is no objection to Professor Bancroft amusing himself in biologic speculation. But one may justifiably object when he claims scientific validity for what is certainly speculative on his part, even though he may try to disguise it by plausible argument, superficial experimentation, and selected reference to scientific literature.

Professor Bancroft's speculations on narcosis have been critically examined and judiciously demolished by V. E. Henderson and G. H. W. Lucas, pharmacologists at the University of Toronto (*J Pharmacol & Exper Therap* 44 253 [Feb] 1932). To their direct experimental refutation of Professor Bancroft's notion that sodium thiocyanate (rhodanate) may antagonize sodium amytal, ether or morphine narcosis, I would like to add my failure on four trials to confirm Professor Bancroft's reported experimental antagonism between sodium thiocyanate and morphine in rabbits. I repeated in detail the experiment described by Professor Bancroft in his paper "The Colloid Chemistry of the Nervous Systems. I. Sodium Thiocyanate Therapy" (*J Physical Chem* 35 1185-1211 [May] 1931, p 1195). I found that the administration of sodium thiocyanate in the manner and amount described by Professor Bancroft definitely did the opposite of what was claimed by him, that is, I found that it *increased* the real narcosis of the morphinized rabbit, in comparison with the control, and that the narcosis

lasted longer than in the control. It is true that at the moment of sodium thiocyanate injection the morphinized rabbit showed evidence of irritation. Sodium thiocyanate is a local irritant. Also it causes methemoglobin formation.

Further experimental refutation of Professor Bancroft's thesis has been furnished by H. E. Guerlac (*Proc Soc Exper Biol & Med* 30 265 [Dec.] 1932). Guerlac found that sodium thiocyanate instead of antagonizing the toxic action of ethyl urethane on the developing eggs of *Arbacia punctulata* definitely increases its lethal effect.

The untoward results of potassium thiocyanate therapy in human beings, especially when used in hypertension, are known to clinicians. There is no reliable evidence to show that sodium thiocyanate may be considered much less toxic. There is no excuse for physicians to employ sodium thiocyanate as proposed by Professor Bancroft on the unconfirmed and unsatisfactory evidence offered by him. While Professor Bancroft may deserve some credit for reproposing on speculative grounds Claude Bernard's coagulation theory of narcosis, it is reprehensible for him to claim scientific validity for the application of his notions to medical fields.

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

PITUITARY DYSFUNCTION

To the Editor—Please state what kind of mental and nervous disturbances occur with hypofunction of the pituitary body and also if known the differences in hypoanterior pituitary secretion and hypoposterior pituitary function. MATTHEW KARASEK, M.D., Shidler, Okla.

ANSWER—Epileptiform seizures occur in animals after partial removal of the pituitary, and epilepsy is said to be a frequent accompaniment of clinical conditions in which an insufficiency of the pituitary, either of the anterior lobe or of both lobes, is manifest. These seizures sometimes have uncinate gyrus features, that is, disturbances of taste and smell accompany them. Inhabitants of epileptic colonies at least in Illinois, show many features indicative of a deficiency of the growth and sex hormone of the anterior lobe during their growing years.

A deficiency of the anterior lobe occurring in preadolescent years is frequently accompanied by mental attainments quite up to normal and sometimes by precocity. Later there tends to be a slowing down of these processes and in adult years there is a general retardation of mental processes accompanied by somnolence, though the latter may be due to a thyroid deficiency which seems to occur as a sequel to pituitary deficiency of long standing.

A deficiency of the growth and sex hormone in preadolescent years results in a lack of development in these spheres. It predisposes the victims to inferiority complexes because of their physical and sexual handicaps.

The acidophilic cells of the anterior lobe elaborate a growth hormone which has a powerful influence in the growth and development of the skeletal system and the voluntary muscles, a sex hormone—or maybe two or three of these—which has to do with the development and function of the sexual apparatus. It is not certain whether there is one sex hormone or more elaborated by the basophilic cells of the anterior lobe. Whatever the number of the sex hormones, their function is fairly well understood. They first stimulate the graafian follicles to complete maturation. This is said to be due to prolactin A or rho I. They initiate or stimulate the development of the corpus luteum and the production of its hormone, progesterone. This is brought about by the luteinizing hormone, prolactin B or rho II. The anterior lobe is referred to as the motor of the ovary. There is probably another hormone or it may be the sex hormone which has to do with the stimulation of testicular. German workers assert that they have isolated a

fat metabolism hormone. The anterior lobe has a profound influence on the thyroid, parathyroid and suprarenal cortex. This influence is probably exerted by the basophilic cells. In addition to the growth and sex hormones, the anterior lobe is also thought to have considerable influence in controlling body temperature.

The posterior lobe presides over carbohydrate and water metabolism and is concerned with the contractions of the involuntary muscles and the secretion of urine. A deficiency of this lobe is believed to be responsible for the polydipsia, polyphagia and polyuria so often seen in pituitary deficiency. Extract of posterior lobe gives the greatest possible relief in diabetes insipidus. The pars intermedia is more closely allied with the posterior lobe. It has lately been thought to elaborate a hormone controlling, or at least concerned with, pigment metabolism.

Overgrowth and hyperfunction of the anterior lobe, occurring in adult years and accompanied by signs of acromegaly, are associated first with nervousness and irritability. Later periods of depression occur. The nervous manifestations may be due to an infringement of the tumor on neighboring structures and to pressure on and consequent paralysis of various cranial nerves. A tumor of the chromophobe cells of the anterior lobe is a space-occupying lesion which leads to signs of pituitary deficiency, such as menstrual disturbances, accumulation of obesity, somnolence and loss of body hair. Small basophilic adenomas recently reported by Cushing are accompanied by obesity, involving the head, chest and trunk, vascular hypertension, and purplish lineae striae. They are associated with hypertrichosis and amenorrhea and acrocyanosis with cutis marmorata of the extremities. It is often accompanied by hyperglycemia and occasionally by polycythemia. A peculiar softening of the bones of the skeleton has been commonly found at necropsy. Cushing is of the opinion that this is not an uncommon syndrome.

TUBERCULOSIS AND WASSERMANN FAST SYPHILIS

To the Editor—A white woman aged 25, who has far advanced pulmonary tuberculosis with involvement of both lungs has been under my care since June, 1930. Her Wassermann reaction, June 18, 1930, was four plus. Since then she has had thirty-four injections of nearsphenamine (the first twenty of which were of 0.6 Gm. each, the last fourteen of 0.4 Gm. each), nine intramuscular injections of a bismuth compound 3 grains (0.2 Gm.) of metallic bismuth, and seventy mercury rubs of 1 drachm (4 Gm.) each of the official 50 per cent mercury ointment. She has just finished a six weeks course of mercury rubs included in the foregoing. Her Wassermann reaction April 12, 1932, was three plus, and has been negative only once, May 28, 1931, since treatment was begun. Spinal fluid examination Jan. 10, 1932, showed the Wassermann reaction negative and a cell count of 6. A colloidal gold and globulin estimation were not done. Her tuberculosis has improved clinically and on roentgen examination. She has gained 24½ pounds (11 kg.) and for the last two months the temperature has ranged from 99.2 to 99.4 F. in the afternoon. Her only symptom or sign referable to the central nervous system is an occipital headache worse at night for the last three years but somewhat better for the last six months. The cardiovascular examination is essentially negative, the blood pressure being normal, there is no cardiac enlargement, no accentuation of the aortic second sounds nor murmurs. What further procedure would you recommend at this time in order to reverse the Wassermann reaction to negative? Do you consider it absolutely essential to reverse the Wassermann reaction? Do you consider this a case of malignant syphilis or a defense mechanism on the patient's part? When would you reexamine the spinal fluid? And last, what effect do you think the tuberculosis has on the syphilitic infection? Please omit name and city. M.D., North Carolina

ANSWER—The only positive clinical sign that might bear a relationship to this patient's syphilis is the occipital headache. In the absence of any other clinical evidence of visceral degeneration, apart from the pulmonary tuberculosis, that might be attributed to latent syphilis and be contributing to the persistent positive Wassermann reaction, this headache must be regarded with suspicion as possibly being a part of an early neurosyphilis. Although the spinal fluid is now negative it should be watched along with the blood Wassermann between courses, in order to note any early serologic or cytologic changes in addition to the colloidal gold and globulin tests.

Further procedure should consist in varying the therapeutic approach by the use of bismuth arsenic sulphonate or a liposoluble bismuth preparation to attempt serologic reversal. If this is not successful the use of small doses of arsphenamine in conjunction with a soluble bismuth preparation might be considered if the pulmonary condition does not show any signs of activity. If conservative dosage of these drugs in courses in the order named do not accomplish reversal of the Wassermann reaction the patient should be given a long rest period during which time she should be closely observed clinically for any visible evidence of syphilitic involvement in any of the organ systems, especially the nervous and cardiovascular. If the patient remains symptom free and in good general

health with a persistently positive Wassermann reaction in spite of mixed continued treatment, its absolute reversal is not essential as long as the patient is carefully and regularly observed clinically.

Every case of Wassermann-resistant syphilis is probably one of a grave infection and it is necessary to consider the case from every aspect before considering the fixed reaction an insignificant one.

The tuberculosis is no doubt a factor in contributing to a low constitutional tone on the part of the patient, which may be a factor in the lessened response to chemotherapy. The tuberculous infection also precludes the use of the iodides in the mixed therapeutic regimen and also calls for greater caution in dosage of the drugs used, thereby lessening to a certain degree the intensity of the therapeutic attack.

HOARSENESS AFTER AMMONIA POISONING OR PARALYSIS OF VOCAL CORD

To the Editor—I am writing to ask you about the compensation aspects in the case of a man who was injured here ten months ago by inhaling ammonia vapor and who has not talked above a whisper since that time. This man, aged 63, a yard laborer has been under my observation for the last twenty one months. Previous to this he was working as janitor at one of the mines at an altitude of 6000 feet and had an attack of subterminal pneumonia which lasted several days and which was diagnosed as a coronary thrombosis by his physician. Following recovery he went to work at the lower camp here at an altitude of 2,100 feet at a light job. When I first saw him in January, 1931, he gave the additional history of a cough which he had had for two years and a goiter which he had known of for about six years. He had been accustomed to an active outdoor existence all his life with the exception of about three years when he was doing the janitor work. His throat showed the reddening of a chronic pharyngitis. There was a large, firm goiter. The superficial veins of the abdomen and chest, especially on the right side, were prominent. The heart sounds were regular and normal, as were the breath sounds. Palpitation of the abdomen gave negative results, as did rectal examination. One testicle had been removed because of an injury received several years before. He weighed 132 pounds (60 Kg). Blood pressure in the right arm was 154/88, and in the left 140/80. Urine examination gave negative results, as did the Wassermann and Kahn tests. A roentgenogram of his chest showed a deviation of the trachea and a widening of the arch of the aorta. With this history and examination in mind I considered the possibility of his having an aneurysm, although the goiter may well be responsible for his cough. During the following summer, a more marked huskiness in his voice developed. In the fall he lost the light job he had and became a yard laborer. Since that time I have seen him do some pretty heavy work without any ill effects, so have come to doubt my diagnosis of an aneurysm. In January, 1932, he was working in a room when an ammonia pipe was accidentally broken and he inhaled a considerable amount of gas before he was removed. He was brought at once to the hospital, where he stayed for about two weeks. He had a marked tracheitis and bronchitis and was treated at first with oxygen and later with benzoin inhalations, hot drinks, acetylsalicylic acid and other measures for the laryngitis, including resting his voice. Fearing the possibility of an esophageal stricture, I had him swallow a thread, but he overcame the difficulty in swallowing in a few days. After his discharge from the hospital he continued vapor inhalations and sprays for a month or more and then came regularly to the office, where I gave him laryngeal inhalations. He was on a tonic of strychnine for a long time. He was an inveterate talker and it was a hard job to try and keep him from whispering. I examined him last in June, at which time he had redness of the epiglottis, paralysis of the right vocal cord, and chronic pharyngitis. I saw him last a few days ago, when he left here. His voice was still a whisper. Could the laryngitis be the result of ammonia poisoning? In my opinion it is from his goiter with a resultant paralysis of the recurrent laryngeal nerve. I have not a large library at hand to look up the subject but from what I can find the results of ammonia poisoning do not last long. Another man, younger, who was injured at the same time as this one, recovered and was back to work the day after. Also, I have not found any reference as to compensation for loss of voice. It is not mentioned in the Alaska statutes, which are modeled after those of Oregon. If you can give me any references as to the compensation phase of this injury, I shall appreciate it. Please omit name.

M D, Alaska

ANSWER—It is not stated whether the patient's larynx was examined prior to the inhalation of ammonia. Had there been a paralysis or paresis of the right vocal cord present prior to this accident, one could attribute the hoarseness to the acute laryngitis set up by the irritant. A cord already moving poorly would be impaired still further, as would the opposing healthy cord. Such a state of affairs could not last long, however, as several weeks would suffice to clear up this condition. One cannot dismiss the fact that a roentgenogram of the chest shows a deviation of the trachea and a widening of the arch of the aorta. The patient has in addition a large thyroid gland. Either the aneurysm or the goiter or both together may be responsible for the paralysis of the right vocal cord and the concomitant hoarseness. Hoarseness lasting longer than six months should not be considered as due to exposure to ammonia. As regards compensation for loss of the voice inquiry seems to show in Illinois at least no stated sum. The general principle

covering a case of loss of voice which is permanent would appear to be that compensation is due if the individual must change his occupation to one yielding less income. The exact amount of compensation would depend on the loss of income.

RELATION OF THYMOL TO THYROID IRRITATION

To the Editor—I have recently seen in the *Ars Medici* (the journal of the American Medical Association of Vienna) an article stating that thymol produces as much thyroid irritation as iodine, even so small a unit as found in tooth pastes such as Euthymol or Listerine. Will you kindly give an opinion on this important subject? (The warning appeared in the *Medizinische Klinik*, April 1, 1932, p 477, it was not abstracted in THE JOURNAL.) WALTON S. SHEPHERD, M D, Charleston, W Va

ANSWER—In the article in the *Medizinische Klinik*, entitled "Warnung vor Thymol und thymolhaltigen Mitteln, Mund-Wassern und Zahnpasten bei Kropfkranken," Prof Ernst Edens of Dusseldorf reports six cases of thyrotoxicosis. Two of the patients were men and four women, and all had for a considerable time used a mouth wash containing thymol, such as Listerine, or a tooth paste containing thymol (Kolynos tooth paste). He reported two cases in 1917 in the same journal (13 807). He has therefore found eight cases in fifteen years which he concludes were due to thymol or were accentuated by its use.

Edens states that his attention was drawn to the possible effects of thymol from reading the report of Robert McCarrison entitled "Further Researches on the Etiology of Endemic Goiter" (*Quart J Med* 2 279, 1908-1909). In this article McCarrison states that endemic goiter is due to a living organism and can be cured by the administration of intestinal antiseptics, notably by thymol. This drug also caused a decrease in the size of the thyroid.

From the photographs in McCarrison's work, Eden drew the conclusion that thymol in some cases caused untoward effects and might cause hyperthyroidism. The cases he reports support this conjecture. The only treatment needed in such cases is cessation of the use of the mouth wash or tooth paste containing thymol. When this use was discontinued, the patients recovered.

His conclusions may be correct, but the report creates the impression of *post hoc ergo propter hoc* logic. In no case has Eden again administered thymol to patients who have been cured, to verify his conclusions. On the other hand, it cannot be said certainly that thymol may not in some cases cause such a condition. It is possible, but it seems improbable.

Thymol is a phenol. Thyroxine is an iodized phenol derivative, but there is no evidence except that given by Eden that thymol may cause an increase in thyroxine or that, by itself, thymol has any thyroxine action or other effect on the thyroid.

Because of the widespread use of thymol in the treatment of hookworm disease and in mouthwashes, it seems that any such action would have been observed long ago. This opinion, however, should not prevent observation and study of such possibility.

Eden reports these cases as a warning. The physician, he says, should think of the possibility of thymol doing harm and make inquiries concerning the use of medicines and beverages of unknown composition.

DERMATITIS IN INDUSTRY

To the Editor—A local industrial plant engaged in printing cloth has been having some trouble as the result of a dermatitis developing on the forearms and hands of the employees, particularly new ones. These men use rubber gloves while working in the chemicals and dyes known to them as "vat colors," "naphthol salts" and "aniline black." The chemicals used are acetic acid, stearic acid, ammonium hydroxide, denatured ethyl alcohol, aniline hydrochloride, aniline oil, glycerin, glycerin, pine oil, paraphenylenediamine, rongalite (sodium sulfoxylate formaldehyde), soda ash (contains about 3 per cent caustic soda), chlorate of soda, yellow prussiate of soda, caustic soda, tannic acid, chlorinated lime potassium carbonate, zinc oxide and chrome (sodium bichromate). The vat colors used are naphthol salt colors, basic colors, rapidogen colors and aniline black. If you can give me the benefit of any study you have carried out or experiments done by any of the Eastern centers where they have had an opportunity to study such cases, I shall greatly appreciate the information.

JAMES L. ANDERSON, M D, Greenville, S C

ANSWER—Almost without exception, the several substances listed in this query have individually been charged with the causation of skin diseases under industrial conditions. Although no mention is made of the quantities of any one substance, it is presumed from a general knowledge that some are in such traces as to be below the threshold of practical damage, except on the basis of sensitization. Recently, the contention has been made that all industrial dermatitis is allergic in nature. In addition, the rubber gloves used for protection may be the source of injury. In an article on industrial dermatoses in

THE JOURNAL, Sept. 17, 1932, Osborne and Putnam related their observation that accelerators in rubber curing may cause dermatitis in the glove wearer. Aside from activities in any particular centers, reference may be made to the following recent publications:

- Knowles F C Trade Dermatoses, *Bull Am A Indust Phys & Surg* 6:7 (Feb.) 1932
 Lloch B Occupational Skin Diseases from the Biological Point of View *J State Med* 38 373 (July) 1930 abstr *J Indust Hyg* 12 226 (Dec.) 1930
 McCord C P What Determines Compensability for Skin Diseases Among Industrial Workers? *Proc Internat A Indust Accident Boards and Commissions* 1932 Bureau of Labor Statistics Department of Labor Washington D C
 White R P Modern Views on Some Aspects of the Occupational Dermatoses *J Indust Hyg* 8 367 (Sept.) 1926
 Sulzberger M B and Wise Fred The Contact or Patch Test in Dermatology Its Uses Advantages and Limitations, *Arch Dermat & Syph* 23 519 (March) 1931

The abstract section of the *Journal of Industrial Hygiene* contains general discussions of these and related matters.

The suggestion is made that workers repeatedly exhibiting a dermatitis be patch tested by means of the technic mentioned in several of the cited publications. If mixtures of several dyeing solutions cause the dermatitis, further tests should be carried out with individual constituents, until the ultimate cause or causes are disclosed. It is predictable that more than one substance will prove to be the offenders. Paraphenylenediamine is a common source of dermatitis and asthma.

PINWORMS

To the Editor—A girl aged 11 has had pinworms for the last four years. She was hospitalized for two weeks once, at which time she received santonin by mouth and dilute mercuric chloride by rectum. The worms returned in a few days. She has been treated with santonin and a proprietary remedy by mouth at different times and with quassia, potassium permanganate and lime water by rectum at different times all to no avail. She had acute appendicitis two months ago and in the appendix were found many pinworms. Ether was the anesthetic used. For two weeks following the operation no worms were seen. Since that time they have returned in borders. Those that appeared at the rectum are much tougher and larger than those that were found in the appendix. Another santonin and quassia course of treatment was given to no avail. I should like to know why there was an apparent disappearance for two weeks following the operation. Can you suggest another mode of treatment? Please omit name.

M D Maryland

ANSWER—Possibly cecal stasis following the appendectomy might explain the temporary absence of the worms. The rectal administration of 4 ounces of a strong salt solution (2 tablespoonfuls of salt to a pint of water) injected at the time when itching is felt will not only relieve itching but also help in the destruction of the worms that have found their way into the rectum. It is useless to inject the salt solution when the pruritus is not felt. To secure ultimate eradication of the worms, prevention of auto-infestation is the most important item, as the vicious circle that perpetuates the infestation consists of itching due to the wriggling movements of the gravid females followed by scratching and contamination of fingers, through them of food the ingested ova hatching in the duodenum the worms living in the cecum and descending into the rectum for the purpose of laying eggs. Hence the hands must be washed thoroughly every time the surface of the body or an undergarment is touched. The wearing of closed drawers will help to prevent scratching of the anal region. Any laxness in scrupulous avoidance of contamination of the fingers with the invisible eggs is liable to be followed by vexatious reinfestation.

POST TRAUMATIC SPONDYLITIS

To the Editor—I have a patient a farmer aged 30 who fell on his shoulders in April 1931. For three days he had severe pain in his back after which the condition cleared up somewhat. Then in a few weeks he began having pain in the lower part of his back and in his left leg. The pain all disappeared on lying down. A roentgenogram taken recently shows a compression fracture of the fifth lumbar vertebra. I have put him to bed with his back arched slightly and he is quite comfortable. How long should I leave him there and what kind of a brace should he wear when he does get up. What is the prognosis as to complete freedom from pain. Please omit name and address.

M D Illinois

ANSWER—This may be a case of Kummel's disease or post-traumatic spondylitis. It is questionable what would have been disclosed if roentgenograms had been made in two projections immediately after the accident.

The pain in the patient's leg is evidently due to so-called sciatic neuritis of the sciatic syndrome. It is more common to have the first lumbar vertebra involved than the fifth. There is evidently a peripheral element as indicated by the relief from pain on lying down. It is questionable what the duration will be but it will probably be months.

The treatment to be considered may be divided into non-operative and operative. The former includes hyperextension on a curved Bradford or Whitman frame in the hyperextension frame or bed of Rogers, or by the methods of Davis or Jones. A plaster-of-paris cast followed by a Taylor spine brace with a U band should be beneficial. It may be necessary to perform a fusion operation at the lumbosacral junction. The prognosis should be good.

ETHYL GASOLINE POISONING OR SYPHILIS

To the Editor—An ex service man aged 40 driver of a gasoline delivery truck handling quantities of ethyl gasoline and subjected to constant invasion of the driver's compartment of the truck by motor exhaust gases was seized Sept. 21 1932 with severe left frontoparietal headache dizziness general weakness and slight somnolence. The examination September 23 disclosed diplopia, right ptosis and external squint. There was marked unsteadiness in walking. The patellar reflex was + + + +. The Romberg test revealed slight swaying, and the gait was slightly ataxic. The tongue slightly deviated to the right on protrusion. Fever was absent. The pulse was 80. The pupils were of the Argyll Robertson type. The blood Wassermann reaction was + + + +. There was no basophilia. No paresthesias were discernible. The blood picture was normal. Weakness in walking rapidly progressed until October 8 when he could walk only when more than half supported. October 5 the knee jerks had completely disappeared. Ptosis of the left lid and paresthesias in the legs had appeared. The patient previously had always been in vigorous health with no serious illnesses. He had gonorrhea fifteen years before of moderate severity and quickly cured. He had no knowledge of any genital lesion at any time. He was married and had one healthy son 12 years of age. His wife had had no other pregnancies. Examination of the eyegrounds September 29, disclosed a small area of pigmented retinitis in the left eye. There was no papillitis. The patient said that the left eye had been 'weak' for several years. He occasionally drank to slight excess. No blood examinations were made on the wife or the child. No spinal puncture was made. He had extensive pyorrhea. Three abscessed teeth had been extracted. After several days of anxious speculation and study it was decided to institute active antisyphilitic treatment. September 29 October 5 and October 8 he was given 0.5 0.9 and 0.9 Gm of neoarsphenamine intravenously, during which time the ataxia increased until he could not walk at all without much support on October 8 the knee jerk disappearing on October 5. October 11 there was a sharp enterocolitis lasting forty eight hours and marked gingivitis and salivation lasting two weeks. October 17 23 and 31 and November 7 he received 1 grain (0.065 Gm.) of mercuric salicylate intramuscularly. On this date November 7 he walked well without a cane or other assistance, though somewhat ataxic. The Romberg sign was slightly +. Left ptosis was complete right ptosis was present in slight degree. What are the probabilities as to the cause of this recent acute encephalitis? What should be the future treatment? I have considered the use of iodides and of sodium thiosulphate. Is there good reason for strongly suspecting lead poisoning as the cause of illness? If so what would be the determining factors. Does the apparent rapid amelioration of symptoms point away from syphilis as the cause? Please omit name and address.

M D Pennsylvania

ANSWER—No cases of lead poisoning in drivers of trucks transporting ethyl gasoline have as yet been definitely established. It would be of interest to have the patient's excreta analyzed for lead. But, except on the basis of a positive finding, there is no ground for considering lead poisoning as a factor superimposed on syphilis in this case.

SOFT TEETH AND SOFT WATER IN SCOTLAND

To the Editor—Recently I heard that the explanation of the fact that the people of Scotland in general have poorer teeth and to a noticeable extent lose the teeth at a much earlier age than is the case in the United States is that the water in Scotland is much softer. From personal observation I know that dental caries is much more evident in Great Britain than in this country. Can you state whether this is in appreciable degree due to the softness of the water rather than to less attention to dental care in European countries? Please omit name.

M D, California.

ANSWER—The relationship of the incidence of caries to the hardness of the water used for drinking was reviewed in the *Fortschritte der Zahnheilkunde* 7 348. On the assumption that more than 6 parts of calcium salts in 100,000 parts of water constitutes a hard water, Röse found that the percentage of wholly healthy teeth varied from 13 to 43 of those who consumed soft water and from 4.3 to 20.2 of those who drank hard water. Walter reported 36 per cent caries in a group using water with a low percentage (672 parts per hundred thousand) of lime salts and 18 per cent caries in another group drinking a very hard water (1596 parts lime salts per hundred thousand). Figures quoted from Rogger and Lauener are contradictory and fail to support the conclusions of Röse and Walter that caries varies inversely with the hardness of the water used for drinking purposes. The author of the review, Turkheim, suggests that the mineral content of the food consumed may be of much greater importance than the hardness of the water and that this was not given much consideration in these papers.

Hardness of the water does play a part, although of minor importance, in the etiology of dental caries. The cause for the well known high incidence of tooth decay in England and Scotland, without doubt, has but little to do with the softness of the water used there. Rather is it to be found, as suggested, in the attitude toward dental care, the character and composition of the food consumed, and the nutritional and hygienic habits of the inhabitants.

AMYOTROPHIC LATERAL SCLEROSIS

To the Editor—It is the contention of an applicant for veterans' compensation that "amyotrophic lateral sclerosis and progressive muscular atrophy" may be classified with encephalitis and spinal meningitis in the "preferred group" of laws of 1930. Are the pathologic changes in cord and motor nerve endings and the end results in the symptomatology, that is, the amount of paralysis, and so on, the same? Is this correct? The textbooks deal with lateral sclerosis and muscular atrophy lightly and are most confusing. Please omit name.

M D, New York

ANSWER—The rules governing compensation for progressive muscular atrophy and amyotrophic lateral sclerosis are identical with those that apply in the case of epidemic encephalitis. If these diseases were manifest before Jan. 1, 1925, service connection is assumed, the amount of compensation is determined on the basis of the actual degree of functional disability. Progressive muscular atrophy and amyotrophic lateral sclerosis are both characterized by progressive degeneration of the lower motor neurons, i. e., the anterior horn cells of the cord and the peripheral motor nerves, with consequent atrophy and loss of power in the muscles supplied by the affected neurons. In amyotrophic lateral sclerosis there is, in addition, degeneration of upper motor neurons, i. e., the giant cells of the motor area of the cortex of the brain and their axis cylinders, which constitute the pyramidal tracts and travel down the cord in the lateral column. As a result of this element in the disease there is a spastic condition of muscles that are not undergoing atrophy, with increased tendon reflexes, frequently clonus, and an extensor type (Babinski sign) of plantar reflex.

FARASTAN

To the Editor—The pages of the *American Journal of the Medical Sciences* regularly carry advertising of Farastan, which is said to be iodo-cinchophen. Kindly advise me as to the official status of this substance. Is it known to produce hepatitis, such as is believed to occur following the use of cinchophen?

M D, New York

ANSWER—Farastan was the subject of an adverse report by the Council on Pharmacy and Chemistry (*THE JOURNAL*, Feb. 15, 1930, p. 484). The name is a proprietary designation under which the Farastan Company markets its preparation of iodine and cinchophen, which is claimed to contain approximately 33 per cent of iodine. As the Council pertinently remarked, there is no evidence that the routine use of cinchophen and iodide in fixed proportions (or in any proportions) is desirable or rational. Usually the conditions that require cinchophen do not require the simultaneous administration of the iodides, and vice versa. It appears particularly undesirable and even dangerous to encourage the routine prescribing of cinchophen, which should be used only for short periods, with an iodide compound, which should be continued over a long period. If the administration of iodide together with cinchophen should be indicated or desirable, these can be given in separate doses. There is no reason to suppose that the likelihood of producing hepatitis from Farastan is any less than that from an equivalent amount of cinchophen.

TEST FOR BILE IN URINE

To the Editor—The textbook on physiology by Landois and Stirling mentions a simple test for bile in the urine. A pinch of flowers of sulphur is sprinkled on the surface of the urine, and, if bile is present, the sulphur sinks to the bottom. Some authors have gone so far as to call the delicacy of this test "miraculous." Now I have sprinkled flowers of sulphur in urine loaded with bile, and have yet to see the powder sink at once to the bottom. Shall I believe my own eyes or the authorities? Perhaps you can help me out. Please omit name.

M D, New York

ANSWER—Either bile pigments or bile acid salts or both may be excreted into the urine, hence it is necessary to test for both.

The test with sublimed sulphur (flowers of sulphur) is a surface tension test and is a test for bile acid salts only and not for bile pigments. The presence of bile salts (0.01 per cent or more) lowers the surface tension enough to cause the sulphur to sink rapidly. Settling after agitation is inconclusive. Pettenkofer's test is the most satisfactory one for bile salts in the urine.

These tests for bile salts are often negative in clinical jaundice, even when much bile pigment is present. This negative reaction for the bile salts is due to the fact that they are formed at a slow rate and normally conserved by resorption from the intestinal tract. Only when the threshold in the blood exceeds the renal threshold for bile salts do they appear in the urine.

The tests for bile pigments most commonly used are the foam and Gmelin-Rosenbach tests. From the foregoing observations it is obvious that the tests for bile pigments should always be done and that their presence has the same significance as the presence of the bile acids or their salts. The test with sublimed sulphur is positive only when the bile salts exceed 0.01 per cent.

PARALYSIS OF PALATE AFTER DIPHTHERIA INFECTION

To the Editor—Recently I have had two patients affected by a paralysis of the soft palate, one of them also having an ocular involvement, there being a total paralysis of accommodation. The conditions followed throat infections, one having a severe streptococcal infection and the other a milder mixed infection. The two patients live in the same apartment house and work in the same building. The severe case preceded the other by several weeks. Is it unusual to have such paralysis following other than diphtheria infection? Is a diphtheria carrier subject to it without having the disease? Is exercise contraindicated before the paralysis clears? Please do not publish my name.

M D

ANSWER—With this type of cranial nerve involvement it is almost certain that infection with the diphtheria bacillus also existed. It is extremely unusual to have such involvement in any other infection. To our knowledge a mere carrier would not be so affected. It is well to be slow in allowing exercise, as there may be some involvement of the vagus.

ARTHRITIS DEFORMANS

To the Editor—A woman, aged 50, has had arthritis deformans for twenty years. There has been a progressive increase in muscular atrophy and deformity of the hands and spine during this time, in spite of treatment at various clinics throughout the country. Many possible foci of infection have already been removed, especially in the teeth and the tonsils. Her present condition is ankylosis of the spine in such a curve that her head is fixed on her chest, making it difficult to breathe and to eat. There is some pain in all the diseased joints, and a great amount of pain in her back, on the right side, over the lower ribs. The muscle in this region is unusually hard to the touch, and there is great tenderness on pressure. Some one has convinced the patient that her spine can be forcibly straightened out sufficiently to allow her head to become upright. She feels that if she were ankylosed in that position she would be likely to produce a much more rapid progress in the course of the disease, but I would appreciate your advice as to the practicability of this or any other procedure.

LOUIS LEFEVRE, M D, Muskegon, Mich.

ANSWER—This is evidently a case of progressive arthritis deformans with marked atrophic symptoms. The following are factors in the treatment that may be of benefit: (1) gradual traction in the line of deformity, (2) wedged casts, (3) a turn-buckle jacket, (4) ether anesthesia, (5) vaccine for pains, (6) posture training and (7) physical therapy, consisting of radiant heat, gentle massage, very gentle manipulation and the sinusoidal current to improve muscle tone.

BLOOD PRESSURE IN PREGNANCY

To the Editor—What is the explanation of a blood pressure reading of 80 systolic, 50 diastolic, in a perfectly healthy young woman of 25 who consulted me on account of an early pregnancy? There is no asthenia or neurosis. Weight gain is progressing normally under the circumstances and is normal for the age and height. What is the prospect of this condition producing complications of labor or puerperium? Please omit name.

M D, Iowa

ANSWER—A woman may be perfectly healthy and have a surprisingly low blood pressure. Some athletes have a low blood pressure. Ordinarily during pregnancy the blood pressure runs from 105 to 115 systolic with the usual 3-2-1 ratio of pulse pressure. Any pressure below 100 may be considered unusual, possibly abnormal, but the patients do not always suffer. Anemia, tuberculosis, neurasthenia, enteroptosis, heart disease, focal infections and endocrinopathy should always be looked for in cases of hypotonia and these conditions treated as well as possible. Blood pressures as low as 60 systolic and 40 diastolic have been reported as not being followed by trouble, although it seems that these women are likely to be obstetrically unfit. They show effort-exhaustion, cold hands and feet, acrocyanosis, headaches, vertigo, sleepiness, fainting spells and unbalanced emotions. They are liable to abort or have premature labor, and the labor is often complicated by muscular weakness with prolongation. The babies are apt to be small.

P. F. Williams wrote a good paper on hypotonia in pregnancy (*Am J Obst & Gynec* 18:546 [Oct] 1929).

UNILATERAL NASAL DISCHARGE

To the Editor—I am taking care of a child who has had a unilateral nasal discharge for three years. She has had an antrum operation on the same side. She has had skin tests. The culture is negative for Klebs Löffler bacilli but there is still a watery nonirritating discharge. How common is this and what can be done about it? Please omit name.

M D, Massachusetts

ANSWER—A unilateral nasal discharge persisting over a long period of time, especially in a child, is suggestive of the possibility of a foreign body. This is particularly true if any suppurative condition present in one of the sinuses has been properly treated, or if no suppuration in any of the sinuses can be found by transillumination or roentgen examination. A thin, watery discharge from the nose is often due to a hyperesthetic rhinitis but it is unusual to find this condition in one side of the nose only. It is rather uncommon for this thin secretion to be present after radical operative treatment of the maxillary sinuses. Roentgenograms of the nasal cavities should be made carefully in the effort to decide definitely whether a foreign body of any sort is present which produces a constant irritation. Protein sensitization tests might be made, but the skin tests are not always positive even when there is a protein sensitivity of one sort or another. The use of a bland oil, such as white liquid petrolatum, instilled into the nose three or four times a day may allay a local irritation of the mucous membrane if no foreign body is present.

CHRYSAROBIN IN PSORIASIS

To the Editor—In *Queries and Minor Notes* (THE JOURNAL Dec. 17 1932 p 2134) the question was raised about the use of arsenic in the treatment of psoriasis in children. I have had many older patients with one or many previous attacks coming on usually in the cold months in which some form of chrysophanic acid was used locally and always with personally supervised application. Why do you not mention this drug in your answer? In my hands it has been by all means the most valuable remedy for the attack. Secondly, does diet play any part in the treatment? Please omit name.

M D New York.

ANSWER—Chrysophanic acid preparations were not mentioned because no attempt was made to cover all methods of treatment for psoriasis and because the objections to the chrysophanic preparations in children are greater than they are in adults. The difficulty of preventing children from getting the ointment on their fingers and then rubbing the fingers in their eyes is the chief objection. If these preparations are used in children they should be weak. Five-tenths per cent ointment of chrysarobin is often sufficient. The danger of dermatitis is much greater than in adults. Dietetic treatment of psoriasis, in the experience of most dermatologists, has been unsuccessful.

ABSORPTION OF BORIC ACID FROM SKIN

To the Editor—Please advise me whether there is any danger of absorption of borax enough to cause systemic trouble from the continued use for a few months of the following preparations for ringworm of the scalp in a boy aged 7 years. Preparation 1. 2 per cent borax solution in water and alcohol used on the scalp once daily. Preparation 2. boric glyceride 50 per cent rubbed into the affected area twice daily. I obtained this treatment from Shoemaker's *Diseases of the Skin* and he says there are no poisonous qualities. The editorial on unappreciated paths of absorption (THE JOURNAL Dec 8 1928 p 1807) would also lead me to believe that sodium borate is not absorbed whereas boric acid is. How ever I should like to be convinced again as I have an enigmatic case in which this treatment has been used for some time. Please omit name and address.

M D New Mexico

ANSWER—The statement is correct that boric acid may be absorbed from the skin while sodium borate is not. This applies only however to normal skin. When the skin is excoriated or diseased both agents may become absorbed. Unless the lesion is extensive, however it is doubtful whether any harm will come from these relatively nontoxic agents.

DETAILED DENTITION AND ENDOCRINE DISORDERS

To the Editor—I have a child about 5 years of age whose family history is entirely negative other than the fact that during gestation period the mother had a basal metabolic rate of minus 30 and received thyroid extract in sufficient doses to counteract this low rate. At the present time this child has only six or eight teeth and roentgenograms of the maxilla and mandible show that there are no formations of any type. Please give me any suggestions or information that you may have on this subject. Please omit name.

M D Texas

ANSWER—Since endocrine disturbance especially deficiency of the thyroid is one of the accepted causes for the probable explanation of dentition incompleteness the prenatal low basal metabolic rate of the mother would seem to be particularly significant in this case. At 5 years all the deciduous teeth should be wholly erupted and many of the permanent teeth calcified to a degree that

would produce a record in the roentgenogram. It is possible, however, that there may be present elementary and uncalcified tooth germs which do not show on the films, but it seems likely that this is a case of the congenital absence of many teeth, a condition that is extremely rare. Treatment is based largely on the suspected etiology, as endocrine therapy and ultraviolet radiation (both local and general). Other evidences of endocrine disease should be of some value in determining the exact nature of the deficiency, if any. Eventually, prosthetic substitutes for the missing teeth will have to be supplied.

CRITERIA OF CURE IN LEPROSY

To the Editor—Can you tell me when a patient is actually cured of leprosy? I have several who have been under treatment for a long time and have no sign or symptom whatever of the disease except that they have some anesthesia in spots. In many of my patients the amount of anesthesia is greatly reduced, but I have yet to see a case in which it has absolutely disappeared. Recently I have been wondering whether there may not be some permanent damage done to the nerves as there is to some of the other tissues. If you can give me any help I will be really grateful for the treatment is hard for these patients every week.

C E BOUSFIELD, M D Chaoyang China

ANSWER—Leprologists hesitate to pronounce convalescent lepers "cured," since there has not been described an acceptable test to determine the disappearance of the disease.

Patients presumed to have recovered from leprosy are released from various leprosariums on arbitrarily adopted criteria dependent on a period of months or years during which the patient has been free from symptoms as well as presumably free from *Mycobacterium leprae*.

Lepers having the skin type of leprosy may return almost completely to normal. Lepers of the nerve and mixed types usually retain their deformities and the majority of the anesthesias, destruction of nerve trunks or nerve fibers may be demonstrated histologically, nerve regeneration is relatively infrequent and incomplete.

SCIATIC INFLAMMATION AND SPINAL ANESTHESIA

To the Editor—I have a patient who was operated on in August 1932 for acute appendicitis under spinal anesthesia. The operation lasted twenty minutes. There were no complications except violent headache for three days unrelieved by morphine or sodium amytal. For the past two months the patient has complained of severe sciatica, on the right side whenever she remains seated for any length of time. Tonsillectomy was performed in childhood. The teeth are sound. The Wassermann and Kahn reactions are negative. Please advise as to pathologic changes suspected and the treatment.

A. L. DELANEY, M D Livingston Texas

ANSWER—It is improbable that there is any connection whatever between the "sciatica" and spinal anesthesia. The violent headache that followed was probably due to the seepage of cerebrospinal fluid following the lumbar puncture. Concerning the treatment of so-called sciatic neuritis or the sciatic syndrome, one would suggest absolute recumbence in bed with leg or pelvic traction, with the foot of the bed elevated and a weight suspended from a traction rope. Physical therapy consisting of radiant heat and gentle massage should be beneficial. Diathermy should be tried and continued unless it aggravates the symptoms.

SYNTHALIN IN DIABETES

To the Editor—Kindly give the status of the use of synthalin in the treatment of diabetes mellitus. Are there any ill effects of long continued usage? Please omit name.

M D Illinois

ANSWER—It is the general opinion at present that synthalin is of little or no actual value in the treatment of diabetes mellitus. When it was first brought out it was noted that following its administration the excretion of sugar in some cases was diminished. However, many such patients who were improved complained of nausea or vomiting. Later it was discovered that synthalin was a liver toxin and most observers believed that the apparently good effects were actually the result of damage to the liver. Certainly the initial promise of its usefulness has not been sustained by later investigation. The product has not been accepted by the Council on Pharmacy and Chemistry.

VEHICLE FOR OILY SPRAY

To the Editor—What oil may be prescribed as a vehicle for spray instead of Aeryl and such proprietary preparations?

JAMES W. DAVIS, M D Statesville N C

ANSWER—White liquid petrolatum or any other plain bland oil may be used as a vehicle for an oily spray. Instead of the ordinary atomizer it is necessary to use a nebulizer when using any oily preparation.

New Jersey June Examination

Dr James J McGuire, secretary, New Jersey State Board of Medical Examiners, reports the written examination held in Trenton, June 21-22, 1932 The examination covered 9 subjects and included 90 questions An average of 75 per cent was required to pass Ninety-one candidates were examined, 84 of whom passed and 7 failed The following colleges were represented

College	PASSED	Year Grad	Per Cent

Book Notices

Tenth Scientific Report on the Investigations of the Imperial Cancer Research Fund Under the Direction of the Royal College of Physicians of London and the Royal College of Surgeons of England. Boards Price 30s 1p 202 with illustrations London Taylor & Francis 1932

This embodies the results of investigations conducted during the past three years. Ludford found that the lowering of resistance to the growth of transplantable tumors is the result of some interference with the function of cells derived from lymphocytes and monocytes, which segregate acid dyes. Such cells appear in large numbers around the margins of reabsorbing tumors and irradiated tumors. The results of these experiments indicate the possible danger in the treatment of cancer with colloids in cases in which the body may be offering some resistance to the malignant growth.

Fould's experiments of the effect of vital staining on the distribution of the Brown-Pearce rabbit tumor led to the observation that tumors are rarely found in the spleen and are relatively uncommon in the lungs and liver. Vital staining with trypan blue greatly increased the incidence of tumors in the spleen, lungs and liver after intravenous inoculation. It is suggested that the spleen in man resists the establishment of secondary deposits by a local mechanism probably dependent on the cells of the reticulo-endothelial system.

Crabtree reports biochemical investigations on respiration and carbohydrate metabolism of the irradiated tumor cells *in vivo* and *in vitro* in which he demonstrated that radium effects a lowering of the respiratory function of cells and, more slowly, of the glycolytic function also. No differential action on the metabolism of tumor tissues, as against normal tissues, was observed as a result of radium irradiation, and the observations failed to support the conception that tumor tissue is inherently more vulnerable than normal tissue to radiation.

In an experimental study of the action of radium, Cramer observed that the application of radium to a precancerous area of skin delays and even inhibits the development of cancer. No evidence was adduced that radium breaks down the resistance of the skin to the development of cancer. In a second series of experiments Cramer studied the therapeutic action of radium and concluded that irradiation of a neoplasm damages both the tumor cells and the tumor bed and that regression of a tumor is brought about by a combination of these two effects.

(This view differs from that of the French school, which explains the therapeutic effect of radium on the basis of a selective destructive action on malignant cells.) Cramer's observations are confirmed by Ludford's cytologic studies, which appear also to indicate that, in addition to the direct effect of radium on malignant cells, changes in stroma, particularly in the blood vessels, play an important part in the regression of malignant tumors. Studies on the differential reaction to trypan blue of normal and malignant cells *in vitro* led Ludford to the conclusion that malignant cells do not segregate trypan blue in the same manner as nonmalignant cells when the two are subject to the action of the dye under identical conditions in tissue cultures. Neither *in vivo* nor *in vitro* do the cells of the filtrable tumors stain vitally like their nonmalignant prototypes. It is suggested that the failure of malignant cells to segregate acid dyes may be due to their impermeability to these substances, or it may be due to some peculiarity of metabolism of the cancer cell or of its colloid state.

Colonio Irrigation By W. Kerr Russell M.D. B.S. Medical Officer in Charge Light and Electrical Departments Miller General Hospital for South-East London. Cloth Price \$3. Pp 191 with 28 illustrations. Baltimore: William Wood & Company 1932.

The author reviews the history of clysters and briefly discusses the anatomy, physiology, bacteriology and parasitology of the colon. The various types and modifications of colonic lavage apparatus and the methods of lavage are discussed in detail and are accompanied by appropriate illustrations. The author considers the short catheter preferable to the long one except when medication is to be injected into the cecum. The Studa chair, he says, or the Gymnocolon apparatus is to be preferred. The physiologic effects, dangers and contraindications of colonic lavage and conditions benefited by it are mentioned, and a list of irrigating solutions with their respective indications is included. The validity of the pathologic role of "autointoxication" must be challenged, the existence of which lacks conclusive proof and toward which colonic lavage is in the main directed. Further, exception is taken to the statement "It is obvious that chronic stagnation of the bowels must lead to a chronic poisoning of the whole system," for every physician of wide experience has surely encountered persons who, while having infrequent evacuations, feel well in all respects. Nor has it been proved beyond peradventure of doubt that "chronic constipation lessens the resistance of the body to infecting organisms." The conditions benefited by lavage, as enumerated by the author, are indeed numerous and highly diversified, the therapeutic rationale in many instances being highly questionable. Again, it has not been proved satisfactorily that mucus present in the return flow of the irrigating medium is due to the cleansing effect of the latter, rather, it is believed that repeated lavage has an irritating effect on the colon and is productive of the mucus secretion. In general, it is felt that the practice of colonic lavage has become too expansive and panacean and its virtues have been exaggerated and overemphasized without adequate clinically controlled studies.

La critica medica nella storia Alessandro Magno. Da Mario Bertolotti. Cloth Pp 413 with 70 illustrations. Turin: Fratelli Bocca Editori [n. d.]

The author has attempted to study the biographic data on Alexander the Great from a medical, biologic and psychologic standpoint. He has arrayed an enormous amount of material and produced a book replete with fine photographs of the Alexandrian period, showing statuary and reproductions of many rare busts and masks of the emperor. An attempt is made to explain the psychology of Alexander the Great by taking into consideration his heredity, constitution and racial characteristics. The author assumes that Alexander was certainly a hyperthyroid type. He bases this conclusion on his mental precocity, prominent forehead, prominent, large jaw and evidence of strong will power. In discussing the character of the young man the author emphasizes his manly interest in the hard physical sports and the stern up-bringing that he received at the hands of his father and under Aristotle. The influence of the Macedonian race, composed of warlike peoples or stern virtues is contrasted with the highly civilized Hellenic people. The author cannot assign any value to the belief that Alexander was homosexual, as some of the contemporary Greeks were. The author feels that, notwithstanding the fact that Alexander

was not inclined to the company of women, he certainly was not a victim of homosexuality.

The character of Alexander may have been influenced by the affliction of wryneck, with which he suffered from early youth. The author points out that one side of the face was larger than the other and that no doubt some disturbance of the neurovascular bundle on that side of the neck may have affected his psychic and nervous reactions. The book contains some interesting descriptions of the fracture of the base of the skull from which Alexander recovered, and the author points out that the character of Alexander after this accident was not the same. He was irritable and suspicious of his friends. A fine description is given of the chest wound received in battle in Persia from which, according to reports by the various physicians that attended him, the author concludes that the emperor must have suffered from empyema. He gives a splendid description of an attack of malaria of the tertian type, which the author has reconstructed from the various historical reports of Alexander's illness.

In writing this book the author accomplished a gigantic task, even if it does not seem to possess any real utility, yet one can hardly escape the conviction that many of the deductions are purely conjectural in the absence of a true accumulation of facts.

Elements of Electrocardiographic Interpretation By Louis N. Katz, A. M. M. D. Physiologist and Director of Cardio-vascular Research, The Michael Reese Hospital, Chicago, and Victor Johnson, Ph. D., Instructor in Physiology, The University of Chicago. Paper, Price, \$1. Pp. 39, with 38 illustrations. Chicago: University of Chicago Press, 1932.

This contains thirty-eight carefully chosen electrocardiograms illustrating various normal and abnormal mechanisms of the heart beat. Such a presentation of the subject is necessarily incomplete and, as stated in the preface, "the outline omits entirely any consideration of etiology, symptomatology, and prognosis of the underlying cardiac pathology." The booklet, however, will be found valuable as supplementary reading for the student of cardiac physiology who depends on a series of lectures or one of the more detailed works on electrocardiography as the major source of his information on the subject.

Community Health Organization: A Manual of Administration and Procedure for Cities of 100,000, With Suggested Modifications for Larger and Smaller Urban Units Edited by Ira V. Hilscock, Professor of Public Health, Yale School of Medicine. Second edition. Cloth. Price, \$2.50. Pp. 261. New York: The Commonwealth Fund, 1932.

This volume summarizes the valuable services that have been rendered to the public by the Committee on Administrative Practice of the American Public Health Association through the studies of community health organization and its efforts to bring some sort of order out of the chaos into which excessive individualism had thrown public health administration. In the earlier portions of the several chapters, in which facts are recorded and fundamental principles discussed, the book is admirable. Health administrators, especially the inexperienced, should not be without it. Unfortunately, like other committees and commissions too well known to need mentioning, the conclusions do not always fit the facts. The principles of organization are excellent as described in the volume, but when details are discussed, especially with respect to personnel and budgets, the committee gets its feet far off the ground. Its schematic outline for health personnel and budget for a city of 100,000 is top-heavy with too much supervisory personnel. In such a department, the health officer would have nothing left to do but to perfect his golf game. To take but one example, the division of vital statistics, the scheme calls for a director and a clerk-draftsman, at combined salaries of \$4,500 to \$5,500. In such a city, if the rates were approximately normal, there would be about 2,200 birth certificates to handle, 1,200 death certificates and perhaps 600 marriage certificates. The cost would exceed \$1 for each certificate, when as a matter of fact the copying, classifying and indexing and making the necessary statistical studies could easily be done by an industrious clerk under the supervision of the health officer and at less than one-third the cost. There are other examples, such as the recommendation for a full time director of the division of venereal disease control, a function that could easily be discharged by the epidemiologist. Forty staff nurses, besides a director and seven

supervisors, are too many. Probably few cities of 100,000 do or may reasonably expect to undertake much in the way of drug control. The laboratory seems heavily overstaffed with three professional workers and a clerk. Probably the authors have been greatly influenced by their association with numerous demonstration and survey projects, in which special recording and research staffs have usually been financed by foundation grants. These are no part of the health organization of the average run of American cities, nor will they be. The practical health officer who has been in the game knows that, while he would enjoy being the boss of a de luxe outfit such as the book describes, he will be lucky if he gets half that, even in times of prosperity. He also knows that he can do a mighty good job of health work on a much less pretentious basis.

Bacteriology for Nurses with a Laboratory Manual By Royall M. Calder, M. D. Instructor and Resident in Medicine. Cloth. Price \$2. Pp. 285 with 52 illustrations. Philadelphia & London: W. B. Saunders Company, 1932.

This is a well conceived and well written textbook. Following brief chapters dealing with the historical phases of bacteriology, the general characteristics of micro-organisms and the fundamentals of infection and resistance, the greater portion of the book is devoted to the bacteriology of communicable diseases classified on the basis of methods of transmission and with particular emphasis on facts that are of value to nurses. A few statements are open to criticism. Toxins are classed as waste products of bacterial growth, colds are definitely stated to be due to a filtrable virus, and *Bacillus enteritidis* is the only member of the paratyphoid group mentioned in connection with food poisoning. The relative insignificance of these criticisms indicates the success the author has attained. The illustrations are considerably above the average of those found in most textbooks. A laboratory manual is included.

Cultivating the Child's Appetite By Charles Anderson Aldrich, M. D., Associate Attending Physician, Children's Memorial Hospital, Chicago. With a foreword by Clifford G. Grulee, M. D., Professor of Pediatrics, Rush Medical College, University of Chicago. Second edition. Cloth. Price \$1.25. Pp. 187. New York: Macmillan Company, 1932.

This edition contains minor changes of the original text and a chapter on developments in the last five years. This additional chapter contains discussions on the relationship of vitamin B to the appetite, the daily amount of milk to be included in the diet, and the influence of body type, gastro-intestinal physiology and endocrine gland secretions on the appetite. The author feels that the modern concept admits the influence of infected tonsils, adenoids and sinuses as a cause of poor appetite and that anemia is probably a potent cause of anorexia. The text contains numerous illustrative examples of the various types of anorexia commonly encountered. The book should prove of value not only to mothers but also to physicians, psychologists and nurses who may have to deal with anorexia in children.

Das Schicksal des Jungentuberkulösen Erwachsenen. Ergebnisse der Heilstättenbehandlung von annähernd 10,000 Männern und Frauen. Von Dr. W. Münchbach, Oberarzt der Heilstätte Friedrichshelm Nr. 49, Tuberkulose-Bibliothek. Beihefte zur Zeitschrift für Tuberkulose. Herausgegeben von Prof. Dr. Lydia Rablowsky. Paper. Price 6.20 marks. Pp. 64 with 8 illustrations. Leipzig: Johann Ambrosius Barth, 1933.

Dr. Münchbach has compiled statistical data on nearly 10,000 patients with pulmonary tuberculosis. They all have been under treatment in two tuberculosis sanatoriums. The end-results are expressed in terms of "able to do normal work," "able to do part-time work," "not able to work," and "dead." It is shown further how long the survival period was following discharge from the sanatorium. It was unavoidable to represent the final results essentially in subjective terms, since the patients were not examined at the end of the observation period but were requested to fill out questionnaires. The observation period was from two to nine years. The patients were grouped according to the anatomic extent of their lesion (Turban-Gerhardt classification), according to the presence or absence of cavities, and according to positive or negative sputum examinations. In addition, there is a group of patients who received pneumothorax treatment. It is probably just about impossible to include finer clinical detail in mass statistics on tuberculosis.

BOOK NOTICES

691

Consequently, the results of such statistics remain unsatisfactory from a clinical point of view. Their value, however, is considerable for health administration. The results of Dr Münchbach's studies cannot be given in abstract, they are necessarily rough averages, to concentrate them further would deprive them of their value. Dr Münchbach's figures translated into human fate produce a gloomy picture indeed, and while nobody would expect the exact reverse, it is distressing to realize that sanatorium treatment has done so little to cure disease and prolong life. Nothing is said about the length of sanatorium treatment beyond the remark that patients who stayed less than six weeks were not included. Since the majority of the patients were supported by *krankenkassen*, it may be assumed that most of them did not stay longer than three months. If this assumption is correct, the present statistics may be accepted as representing the natural course of pulmonary tuberculosis, essentially uninfluenced by anything worthy of the name of phthisiotherapy.

Parents and Sex Education for Parents of Young Children By B C Gruenberg Third edition Cloth Price \$1 Pp 112 New York Viking Press 1932

This book covers sex education in a fairly adequate manner. In reading the pages one finds them not particularly interesting but reliable and constructive. The divisions of the book are not particularly appropriate and it was somewhat hard to find a given piece of information. The book escapes the most flagrant mistakes that are commonly made in sex education and is certainly better than the average.

Das Wesen der Krebskrankheit und ihre kausale Behandlung Von Dr Rudolf Hoosen Paper Price 3.80 marks Pp 56 Leipzig Curt Kahlitzsch 1931

This small monograph includes two distinct subjects: one, a new theory of cancer, the second, a discussion of the use of isamine blue as a therapeutic agent for cancer. The theory is that cancer is due to an increased osmotic pressure in the cancer cells as evidence for which is quoted the work of Cramer and others which shows that cancer tissues contain much more water than the corresponding normal tissues. The other arguments which the author produces to support his theory are not convincing nor is he any more happy in his proof that isamine blue has any value in the treatment of cancer. He acknowledges that transplanted animal tumors cannot be cured. He grants that the patient's skin remains blue for some time which obviously limits the use to advanced cases and he brings forward no definite statistics to prove its effectiveness either alone or in combination with irradiation in the cure of human cancer.

The Thinking Machine By C Judson Herrick Second edition Cloth Price \$3 Pp 374 with 8 illustrations Chicago University of Chicago Press 1932

The first edition of this book attracted wide attention as representing a biologic contribution to an understanding of the functions of the human brain. The author assumes a mechanistic view of human nature but sees therein no destruction of human values. In his second edition he has revised the book critically corrected a few errors and brought the work down to date in the light of recent research.

Trabajos recientes sobre endocrinología y psicología criminal Por el Prof A Lunde Traducción y prólogo del Profesor Mariano Rutz Funes Paper Price 1 peseta 1 p 314 Madrid Javier Morata 1932

This represents an interesting compilation of essays and articles that had been individually published by the writer at previous times. The first of these appeared in 1922. An attempt is made to explain the genesis of criminal characters on anomalies of physical development especially anomalies of the cerebrum. Minor anomalies passed through several generations have a tendency to breed degeneracy. The author has examined many criminals and in the majority of instances finds evidence of some endocrine dysfunction. The suggestion is offered that such dysfunction may be materially lessened by the administration of endocrine gland substances. A lengthy discussion of studies in modern biology follows. The author goes further and shows that the will of man is subconscious and man's actions are subordinated to his individual mechanical

somatic properties. The application of these studies to the science of criminology is in opposition to the usual "moral metaphysics." It will take some time before this new attitude will predominate in courts of justice.

Langs German English Dictionary of Terms Used in Medicine and the Allied Sciences With Their Pronunciation Revised and edited by Milton H Meyers M.D. Neurologist to the Northern Liberties Hospital Philadelphia Fourth edition Fabrikoid. Price \$10 Pp 926 Philadelphia P Blakiston's Son & Company Inc 1932

This dictionary is one of the best available in its field. The present edition contains 3,500 additional words with accurate pronunciations. It can be unhesitatingly recommended for those who require a dictionary of this type.

Patogenia y evolución de la tuberculosis pulmonar Por Dr Manuel Tapia director del Hospital Nacional de Enfermedades Infecciosas Dr Julio Orcaez radiólogo del Hospital Nacional de Enfermedades Infecciosas y Dr Rafael Navarro médico interno del Hospital Nacional de Enfermedades Infecciosas Paper Pp 159 with 140 illustrations Madrid Ruiz Hermanos 1932

This book sets forth the present status of tuberculosis. The initial or primary childhood infection is described, with several plates ably illustrating this lesion. Pulmonary tuberculosis occurring during childhood subsequent to this initial infection is considered an allergic phenomenon. It may follow the introduction of an enormous number of tubercle bacilli or it may occur in a person weakened from some other disease. A relative immunity to tuberculosis exists in adults. An infra-clavicular lesion is a common antecedent to the usual apical lesions. The usual types of tuberculosis in lungs of adults are enumerated and described briefly. For those who care to read more detailed monographs on the subject, a list of recent articles and periodicals dealing with tuberculosis is appended. Radiography has an enormous objective value in the study of pulmonary tuberculosis. It must be remembered that small tuberculous lesions may be elicited on physical examination which do not appear under the fluoroscope or on the roentgenogram, the reverse also is true. The major portion of this monograph consists of photographs and roentgenographic reproductions illustrating the types and degree of pulmonary tuberculosis. These are excellent and are printed on high quality paper.

Functional Disorders of the Large Intestine and Their Treatment By Jacob Buchstein M.D. Instructor in Gastrointestinal Roentgenology Cornell University Medical College Fabrikoid Price \$3 Pp 265 with 100 illustrations New York & London Harper & Brothers 1932

This short book offers a concise and clear presentation of functional disorders of the colon. The author has covered the literature well, and has drawn from it important facts to emphasize the factors of etiology and disturbed physiology. The various sections on treatment give many practical suggestions and measures. In many places the reading matter is simple and clear enough to be understood by the average patient. There are many helpful diagrams and reproductions of roentgenograms.

The Microbiology of Foods By Fred Wilbur Tanner B.S. M.S. Ph.D. Professor of Bacteriology and Head of the Department of Microbiology of Illinois Cloth Price \$7.50 1 p 708 Champaign Ill. Twin City Printing Company 1932

This comprehensive reference work presents the more important facts concerning micro-organisms and their significance in natural and commercially prepared foods, recognized methods for the examination of foods for micro-organisms, the activities of micro-organisms in their desirable and undesirable roles in the preparation and preservation of foods and discussions of methods of commercial and home preparation of foods. The subject matter is brought close to the original work by numerous references. Chapters are devoted to such subjects as food preservation, bacteriology of water and sewage, the microbiology of milk and milk products, fresh fruits and vegetables, sugar and sugar products, meats and meat products, eggs and other common foods, intestinal bacteriology, bacteria, yeasts and molds and their classification, identification and characteristics, and culture mediums and their preparation. The canning of foods and related problems are given especial attention. The volume is valuable to all concerned with the microbiology and preservation of foods and the health problems related to micro-organisms in food.

Medicolegal

Brain Tumor Attributed to Strain of Back

(*Royal Indemnity Co v Land (Ga), 164 S E 492*)

On December 5 or 6, 1930, while standing on a ladder and removing a book weighing about 75 pounds, Land wrenched his back. Previously, according to the testimony, he had been in perfect health. Now he complained of pain between his shoulder blades and assumed a semistooled position. He gave up work a few days later. A physician sent by the patient's employer diagnosed the case as "strained ligaments at the angle of the left scapula" and traumatic neurosis. Under the care of other physicians, however, the patient was operated on for a brain tumor, January 15. A large part of a malignant tumor of the brain was removed. What was left increased in size very rapidly and about three weeks later the patient died.

The widow of the deceased employee instituted proceedings under the workmen's compensation act, contending that the injury sustained by her husband created, or developed and aggravated, the tumor and so caused his death. The industrial commission of Georgia awarded compensation, and on appeal the award was sustained by the superior court of Fulton County. On further appeal, the judgment of that court was affirmed by the court of appeals of Georgia, division number 1.

On behalf of the claimant, the physician who operated testified that there is a feeling among people who deal with this particular type of condition that trauma may have an influence in regard to it, even if it is not the actual production or start of it. Cushing, he testified, says that it cannot be proved that trauma does not have an influence in the development of brain tumor, because in practically every case there is a history of trauma. During a terrific strain, according to this witness, there is a perfectly tremendous engorgement of the vessels of the brain, and the witness could not say that during the cerebral congestion that came with the strain in this case a small, slowly growing tumor was not suddenly caused to become a rapidly growing tumor. The tumor, he thought, could not have existed much longer than from the date of the injury.

The burden, said the industrial commissioner by whom compensation was awarded, should rest on the employers and their insurance carrier to show that, not the injury, but some intervening cause was the cause of death, and he held that the accident itself was as a matter of fact the proximate cause. No witness testified, said the court of appeals, that the tumor was not caused by the injury, and there was admittedly expert testimony that strongly indicated that the contrary was true, and the finding of the industrial commission on questions of fact is final and conclusive if supported by any evidence.

Evidence When Roentgenograms Are Admissible—In an action for damages for personal injuries, certain roentgenograms purporting to show the condition of the plaintiff's leg were admitted in evidence, over the defendant's objection. A proper foundation had not been laid for their introduction, the defendant contended, because no one who took the roentgenograms or saw them taken testified that they "truly represent the objects claimed" or concerning the position of the patient in relation to the tube and plate. If a competent witness, said the Supreme Court of Iowa, states that a roentgenogram correctly portrays the condition of the body to which it relates, or describes the relation of the x-ray machine to the body when a roentgenogram is taken and vouches for the correctness of the position described, the roentgenogram is admissible. Such testimony may be given either by the person who took the roentgenogram or by another witness who knows the facts. In this case the roentgenograms were taken by the superintendent of a hospital, who was skilled in operating x-ray machines. On the witness stand she named the part of the body exposed to the x-ray plate in each exhibit. She said of each exhibit that it showed the part of the body named. She took these roentgenograms for the purposes of the physician who was treating the plaintiff, and it is not likely that the superintendent of a hospital would distort an x-ray negative, knowing that it was going to be used by the physician in attendance on the case. The roentgenograms were properly admitted in evidence.—*Wosoba v Kenyon (Iowa), 243 N W 569*

Malpractice Physician's Liability After Liability of Person Responsible for Injuries Has Been Released—A minor was injured in an automobile accident. Her guardian and parents released the motorist from all liability. Later the guardian sued the defendant physician who had attended the patient, for damages for alleged malpractice in the course of treatment. If an injury is aggravated by unskilful treatment by a physician, said the Supreme Court of Iowa, and if reasonable care was observed in selecting the physician, the aggravation is an element of the damages for which the person responsible for the accident is liable. If the person by whom the injuries were inflicted is released from liability, no action can be maintained thereafter against some other person on the ground that he is responsible for some part of such injuries. A release of the person by whom the injuries were inflicted operates as release of a physician whose malpractice may have aggravated those injuries.—*Phillips v Werdorff (Iowa), 243 N W 525*

Evidence Admissibility of Hospital Records and Charts—In a will contest, the plaintiff claimed that she was the common law wife of the decedent. Over her objection, the trial court admitted in evidence certain charts and records of a hospital in which he had been a patient, in which he was described as a single man. This information was based on statements made by the decedent to hospital attendants. These charts and records, the Supreme Court of Minnesota held, were hearsay, self serving and inadmissible although there may be cases in which the circumstances are such as to make statements so recorded admissible as a part of the res gestae.—*Ghelm v Johnson (Minn), 243 N W 443*

Wills Opinions of Expert Witnesses on Subjects of Common Knowledge—In questions involving insanity or disease expert medical opinion is accepted from necessity, but when an expert's opinion rests on the simple facts of life and everyday occurrences it possesses no more value than the opinion of any other intelligent person. On matters of common knowledge and everyday experiences, the ordinarily intelligent man can make appropriate deductions and derive correct conclusions, and no basis exists for expiation by an expert.—*Dossenbach v Reidhar's Executor (Ky), 51 S W (2d) 465*

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to *THE JOURNAL* in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below

Biologic Effectiveness of Roentgen Rays—Packard studied the biologic effectiveness of roentgen-ray beams of wavelengths 0.05, 0.08 and 1.70 angstrom units, produced at 550, 300 and 12 kilovolts respectively. The test objects were *Drosophila* eggs and mouse tumor tissue. Equal doses of these three qualities of radiation, measured by air ionization chambers produced equal quantitative results. The eggs in their reaction showed complete independence of wavelength. These data confirm the conclusions previously arrived at in experiments with wavelengths of 0.2, 0.3, 0.5 and 0.7 angstrom units.

Regression of Peritoneal Implantations from Cystadenoma—Taylor and Alsop say that the distinguishing clinical features of cases of ovarian papillary cystadenomas with benign peritoneal implants are the gradual development and slow progress of the disease, the marked ascites, and the patient's youth. The onset is insidious but occasionally the abdominal enlargement may follow an attack of acute pain, which the earlier authors interpreted as indicative of rupture and dissemination of the intracystic vegetations. Loss of weight and strength are common, and patients may live for long periods in a state of marked cachexia. Ascites is the rule the fluid being sometimes clear and sometimes sanguineous. Hydrothorax has been reported in cases in which a complete recovery has eventually occurred. In many cases tapping is done repeatedly before the first operation, and not a few patients have undergone a simple celiotomy before the definitive operation for removal of the primary tumor. When ascites is found complicating a slowly progressing ovarian tumor in a young woman a benign papillary cystadenoma with peritoneal implants may be suspected but such a favorable type of growth is extremely rare in women older than 50. The existence of the tumors whose peritoneal dissemination will under certain circumstances disappear has a direct bearing on the treatment of ovarian neoplasms and their recognition either at the operation or in the laboratory, becomes a matter of importance.

The possibility of finding such a tumor is the justification for exploration in certain cases of ovarian growths, particularly in young women, in which clinical examination alone points to an incurable condition. If the type with benign implants is found, disappearance of these may be hoped for if the primary growths are removed. When the tumor is technically inoperable, celiotomy alone may apparently have such a beneficial effect that at a second operation extirpation of the growth is possible. Peritoneal implantations found at operation should be carefully inspected, and if they are thought to be benign, every effort should be made to remove the principal masses of growth. In nearly a third of all reported cases presenting these implants two operations have been performed, because through misinterpretation of the gross observations the first surgeon has limited himself to an exploratory operation. It is possible that at least a few women have been allowed to die unnecessarily because surgeon and pathologist took too hopeless a view of the prognosis. When the benign character of the tissue is first discovered in the laboratory after a simple exploration alone has been performed, serious consideration should be given the advisability of almost immediate reoperation. Should recurrence develop or ascites reappear some time after removal of part of such a growth, a second operation is indicated, for apparently permanent cures have been reported even after a series of four operations. The success of repeated operations led at one time to the recommendation of this procedure as a regular measure for metastatic peritoneal growths of ovarian origin and it was widely known, after its chief advocate, as the Pozzi treatment. Although Pozzi himself believed that celiotomy might benefit even cases of cancer, the evidence at hand leads to the conclusion that second operations are justified only in the benign type of papillary cystadenoma and perhaps sometimes in the most differentiated adenocarcinomas. From the histologic characteristics of these tumors it might be expected that roentgen therapy would be of little value. A failure to produce improvement by roentgen therapy in a case afterward cured by surgery has been reported by Wintz, who pointed out that roentgen therapy might even have the effect of increasing the ascites by irritating the peritoneum. The mistaken inclusion of a few of these cases in a series of supposed carcinomas treated by surgical removal of the primary growths and postoperative roentgen irradiation for the peritoneal metastases may, however, lead to entirely erroneous conclusions as to the value of irradiation in malignant tumors of the ovary.

Fibromyositis—Frank reports three cases of a heretofore undescribed form of diffuse intramural new growth of the corpus uteri, which clinically masquerades under the guise of adenomyoma or diffuse "fibrosis" of the uterus. The point of origin of these tumors remains undetermined, as in all three instances the absence of myomas and the presence of a normal endometrium of both corpus and cervix afforded no clue. From the study of the three cases the following conclusions seem warranted: 1 Diffuse endolymphatic fibromyositis of the uterus, although rare, appears to form a distinct entity. 2 The onset is characterized by marked and repeated uterine hemorrhages. 3 A slow, uniform and symmetrical enlargement of the uterus occurs. 4 From the observations a clinical diagnosis of myoma or adenomyoma is warranted. 5 At operation the observations are such as to justify a similar diagnosis and consequently supravaginal hysterectomy is performed. 6 From the gross specimen, the pathologist makes the diagnosis of diffuse adenomyositis or functional "fibrosis." 7 Microscopic study shows diffuse endolymphatic distribution with no evidence of a primary site. 8 The endometrium is normal. 9 From the cases so far observed, this type of neoplasm appears to be slow growing and with only a moderate degree of clinical malignant changes. No final conclusion as to its radiosensitivity can as yet be offered.

Malignant Tumors—Warren and Gates collected 794 cases of multiple malignant conditions from the literature. These, together with the 189 cases of Major, the 143 of Owen, the 93 of Hard and the 40 of their own make a total of 1,259. On the basis of all statistics, the frequency of multiple malignant conditions is 184 per cent of cancer cases. On the basis of American statistics the frequency is 39 per cent. In the authors' series of 1,078 cancer necropsies, the frequency is 37 per cent. The average duration from the onset of the earlier

tumor to death in their cases is three years. Multiple cancers occur at approximately the same age as single cancers. Multiple malignant tumors occur more frequently than can be explained on the basis of chance. This may be explained by a predisposition or susceptibility to cancer in certain persons, or the action of some factor favoring the development of a malignant condition. The nature of this predisposition is as yet unknown.

Calcium Metabolism and Diseases of Bone—Barr calls attention to the fact that decalcification of the skeleton may arise from diverse causes. It has been observed in association with disuse, as in arthritis, fractures, and other conditions enforcing prolonged and extreme inactivity, also in rickets, hunger and war osteopathies, osteomalacia and celiac rickets, all of which conditions are apparently dependent on a lack or loss of vitamin D and lack of sunlight, and more or less readily controlled by supplying these missing factors. It is seen in association with increased function of the parathyroids, both experimentally following the injection of parathyroid extract and in the clinical condition of osteitis fibrosa cystica, the most effective treatment of which is removal of abnormal parathyroid tissue. The objective finding of decalcification must be carefully differentiated. The terms osteomalacia and osteoporosis, while perhaps sufficiently exact at the time they were devised, have been used as catch baskets for a great variety of obscure clinical conditions and are not helpful in the functional explanation of differences in bone texture. Physiologic considerations in the differentiation of decalcification are not only essential to proper diagnosis but are of the greatest importance in treatment. The comparatively rare diseases in which there is too great calcification in bones have been insufficiently studied. In Paget's disease and in osteosclerosis there is much indirect evidence of disturbances in calcium metabolism.

Diagnosis of Diffuse Endothelial Myeloma—Clopton and Womack believe that while the diagnosis of endothelial myeloma may be made in a certain percentage of cases without resorting to biopsy, often this is not possible. In fact, there are times when even with biopsy the classification of primary medullary tumors of bone is difficult. Whether biopsy is or is not to be done is still a moot point. These tumors are not of sufficiently frequent occurrence to provide statistical data as to the actual danger of this procedure. On purely theoretical grounds and on the observation of a limited number of cases, it may be said that there are perhaps times when this operation has hastened the dissemination of the growth. It would seem, therefore, since these tumors are so markedly radiosensitive, that Ewing's contention for diagnostic radiotherapy is not a bad one. While as yet the authors have had no experience with such a method of attack, it appears to them to be both safe and rational. If, when the diagnosis cannot be made without biopsy, the patient may be given a therapeutic dose of radium or roentgen rays, the reaction is both early and marked in tumors of the endothelial myeloma class. This, of course, is not true of osteomyelitis, and roentgen rays usually have no effect on osteogenic sarcoma.

Tar in Cigaret Smoke and Its Effects—According to McNally, the tar of cigaret smoke contains nicotine, phenolic bodies, pyridine bases, and ammonia, irritants which could account for "cigaret cough," the chronic bronchitis of the cigaret smoker, the leukoplakia in heavy smokers, and the recorded increase of cancer of the lung. The temperature is not an important factor unless the cigaret is burned down to the last centimeter, when the hot smoke becomes more irritating. With a tarry residue of from 4.84 to 15.29 per cent, a definite risk attaches to the smoking of a cigaret. Cigarets should not be smoked too short, as most of the tar and other products of incomplete combustion are retained in the last two centimeters.

Tobacco Tar—Bogen and Loomis describe experiments from which they conclude that the cutaneous application of tar derived from the destructive distillation of tobacco does not possess the irritating and epithelial stimulating properties that lead to the production of neoplastic growths, as tested on the skin of mice and rabbits. That man is similarly unaffected is not proved but is probable, since, although different species show marked differences in their susceptibility to carcinogenic agents, these appear to be quantitative rather than qualitative and a special species susceptibility to particular agents is not yet established. At any rate, in the light of these observations, it

appears highly improbable that the tar obtained during the act of smoking is an important factor in the development of cancer of the oral cavity of man. The prevailing, though not unanimous, clinical observation that cancer of the mouth is unduly prevalent among those accustomed to the use of tobacco is by no means controverted by these observations. Even though the tarry substance settling out from tobacco smoke may fail to show any appreciable carcinogenic properties, there are other factors in the smoking of tobacco which may prove to be potent agents in the production of malignant changes. The mechanical irritation from the presence of a solid object in the mouth may deserve further attention in this connection. The frequent thickening of the lips under the place often occupied by a pipe or a cigaret holder, the development of leukoplakia or smokers' patches on the adjacent mucous membranes, and similar lesions may be early manifestations of reaction to repeated physical trauma which, if continued, will lead to malignant changes. Measures to mitigate the harmful effects of tobacco smoking in the host of persons who find it difficult or impossible to cease the habit, especially in the face of symptoms making this desirable, are obviously to be recommended from the point of view of the medical practitioner. Unfortunately, the commercial claims of interested parties forms no safe guide in this attempt. The blatant claims of "denicotinized" tobacco venders, whose own advertisements disclose an amount of nicotine remaining in the tobacco as great as or greater than that naturally encountered in some tobaccos not so treated, the unfounded appeals for various other brands, and more recently the exploitation of proprietary solutions alleged to "detoxify" the nicotine in a cigaret, which on investigation have been found to be completely without value, emphasize the necessity for caution in accepting information from interested commercial sources. The use of a mechanical device which removes a large part of the tobacco tar but little of the other more active agents in cigaret smoke should receive favorable consideration from medical men only in the event that such tar may be demonstrated to be in itself a source of danger. The results of the authors' investigation indicate that, whatever carcinogenic properties may inhere in the use of tobacco, they cannot well be ascribed to the chemical effect of the tar derived from distillation of the tobacco, and that the patient with leukoplakia or other reasons for fearing susceptibility to cancer of the mouth or lungs would do well not to rely on such a device for his protection.

Differential Diagnosis of Organic Heart Disease—Levene and Reid state that the value of the roentgen ray in the diagnosis of heart disease does not end with the detection of cardiac enlargement. With increasing experience it is possible to derive from careful roentgenographic and roentgenoscopic studies specific information regarding the presence and identification of valvular disease, the integrity of the myocardium and the functional state of the heart as a whole. Distinctive cardiopathies usually produce characteristic alterations in the form of the heart. These changes may be shown by measurement of the heart shadow and of its component parts, revealing not only a gross enlargement of the organ but an altered interrelationship of its chambers, making it frequently possible to identify the anatomic lesions of the heart. Roentgenoscopic examination permits of an appraisal of the functional integrity of the heart and the identification of the various arrhythmias. It is apparent that the interpretation of these changes depends not only on careful roentgenologic technic but equally on a

working knowledge of the clinical and pathologic aspects of heart disease

Carcinoma of Vulva—Friedman outlines a method for the treatment of carcinoma of the vulva by combining surgical endothermy, radium and roentgen rays. The local lesion may be treated by the interstitial insertion of gold radon seeds or by electro-surgical removal. It is preferable to remove the malignant mass with the electro-surgical knife. Only the tumor and the invaded tissues close to the tumor should be excised. After the tumor is removed, the edges of the wound are sewed together. This suture line usually breaks down in varying degrees during the subsequent radium reaction. External irradiation of the tumor bearing area postoperatively is accomplished holding the radium in position with the aid of a wax mold and the sutures have not been removed. The radium tubes are melted into the mold with a melting iron. The radium itself should be filtered heavily with from 3 to 4 mm of lead or its equivalent, and employed in units of from 5 to 25 mg of radium in each tube. Two tubes are placed in the vagina three, if the growth has involved the clitoris. The rest are distributed on the mold to surmount the labia and perineum up to the inguinal fold. From eight to twelve tubes may be employed. The smaller tubes or needles of 5 or 10 mg are preferable because they permit the administration of the dose over a longer period. If a full treatment is to be given, and then repeated in two weeks one can allow 500 mg-hours for each tube. The success of the treatment depends more on the eradication of the sub-born metastatic invasion of the inguinal nodes than on the treatment of the local lesion. The combination of external interstitial irradiation in treating these glands is more successful than surgery alone, or surgery and irradiation. External irradiation is accomplished with high voltage roentgen therapy or the radium pack. When roentgen therapy is employed, the voltage and distance are not as important as the total quantity of radiation administered, because the glands are superficial and do not require deeply penetrating rays to reach them. The utilization of the saturation technic of daily divided doses permits the administration of 250 per cent skin erythema dose in two weeks with no damage to the normal tissues. If a radium pack is used the skin target distance need not exceed 4 cm and a small quantity of radium (from 100 to 200 mg) may be used in order to provide a dose of from 10 000 to 12 000 mg hours over each area. Following this, gold radon seeds should be implanted in the nodes to bring the dose in the tissues up to from 10 to 12 skin erythema doses according to the method of Martin and Quimby. The quantity of radon should be reduced in those areas close to the femoral vessels for fear of thrombosis or rupture.

Shadows of Fenestrated Ribs—Sweany makes a report of his observations on fenestrated and forked ribs in tuberculous patients with emphasis on the interpretation of such shadows in roentgenograms. Although perhaps low, because of the difficulty of making observations on tuberculous patients an incidence of 0.4 per cent was found in nearly 2 500 patients. Seven out of nine were in men and one was bilateral. The third right and the fourth left ribs are most frequently involved. In his experience he found that the fenestrated third and fourth ribs produce annular shadows that may interfere with the interpretation of hilar shadows especially on single plates. The author was able to follow one patient from the early stages of a superimposed abscess on a tuberculous lung to necrosis, of which he presents illustrations.

Cholecystitis—Magner and Hutcheson found streptococci, staphylococci and Bacillus coli most frequently in cultures of the gallbladder wall. There was no significant difference in the frequency with which each of these organisms was isolated. Streptococci were isolated from 37 per cent of the 200 human gallbladders that had been removed by surgical operation, B coli was isolated from 28 per cent of these specimens, staphylococci from 37 per cent, and other bacteria from 24 per cent. In their experimental study, the authors produced chronic cholecystitis in 100 per cent of cases by injecting bladder streptococci under the serous coat of a rabbit's gallbladder. Chronic cholecystitis developed in a small percentage of the experiments in which typical streptococci were injected into the lumen of the gallbladder, the liver and the portal vein, and in a much higher percentage of these experiments when the cystic duct was ligated previous to injection of the organisms. Chronic cholecystitis failed to develop in nineteen cases as the result of simple injection of typical streptococci into the ear vein, in nine experiments in which typical streptococci were injected into the wall of the duodenum, and in seven cases in which typical streptococci were injected into the wall of the appendix. The incidence of the development of cholecystitis as a result of the implantation of streptococci in situations other than the gallbladder wall was increased by previous ligation of the cystic duct. Simple ligation of the cystic duct caused atrophy of the gallbladder mucosa and slight fibrous thickening of the wall in one of eight experiments, calculi were found in the fibrosed gallbladder, in another, the gallbladder showed a true chronic cholecystitis. Ligation of the cystic duct and of the cystic blood vessels produced necrosis of the gallbladder wall, accompanied by a polymorphonuclear infiltration of the necrosing tissues. Cholecystitis did not follow the injection of atypical streptococci into the gallbladder wall the gallbladder lumen or the portal vein. Injection of B coli into the gangrenous cholecystitis. The authors conclude that chronic cholecystitis in man is probably due in most cases, to a streptococcal intramural infection of the gallbladder. In one of their cases B paratyphosus B was isolated in pure culture from the chronically inflamed gallbladder of a patient who had been in the hospital about one year previously suffering from paratyphoid fever. Chronic cholecystitis appeared to be a naturally occurring disease in 2 of 200 untreated rabbits.

Kerion Celsi Associated with Ringworm—Davidson and Gregory report two cases of kerion associated with Trichophyton album. One of the patients also showed a lesion of the eyelid from which the same fungus was isolated. The authors draw attention to the rarity of this condition. The authors were brothers and the probable source of infection was cattle. Each patient developed a trichophytid of the lichenoid type during the third and fourth weeks, respectively, of the disease. The treatment used was boric acid and starch poultices applied to the kerion. The kerion and the eyelid lesions disappeared after the development of the trichophytid. The appearance of

the trichophytid is considered to have been associated with the development of a specific immunity, which was responsible for the spontaneous cure

Insulin in Treatment of Tuberculosis—Heaton points out that little or no benefit may be expected from insulin treatment in acutely active or terminal cases of pulmonary tuberculosis. Insulin has a real place in the treatment of chronic forms of pulmonary tuberculosis, febrile or afebrile, if the patient is undernourished. In some of these cases, insulin is the best drug treatment. A prolonged period of clinical improvement may be initiated by a course of insulin treatment. The dose must be adjusted to suit the patient, the desired effect being an increased appetite without additional unpleasant symptoms. The injection should be given half an hour before the meal. Insulin may be given with benefit over a prolonged period, with intervals of omission. A large proportion of patients fail to experience an increased appetite under insulin treatment and do not gain weight. The author suggests that this failure is due to variations in the dextrose tolerance or insulin sensitivity of these patients. No febrile reactions occurred in the author's sixteen patients. He encountered one case of allergic hypersensitivity, and the giving of the insulin was followed by a hemorrhage. This patient did not have a local reaction to an injection of a solution of crystalline insulin. Some tuberculous patients react to much less insulin than will cause a reaction in a normal person. Therefore the initial dose should not be over 5 units. The special indications for insulin are (1) in preparation for an operation and (2) in loss of weight under artificial pneumothorax.

Polycythemia Vera—Patton and his associates submit evidence for the division of polycythemia vera into an early and an advanced stage. They present data which strongly point to polycythemia vera as the antithesis of pernicious anemia. They conclude that, in normal human blood, cholesterol is unevenly distributed between cells and plasma, there being a greater concentration in the latter. In polycythemia vera there is a considerable increase in the plasma cholesterol, while the cell cholesterol is but slightly altered. In pernicious anemia there is a decided decrease in the plasma cholesterol and, in the more severe cases, a less striking decrease in the cell cholesterol. Cholesterol values for whole blood, particularly in the advanced stage of polycythemia vera, are of little significance. With the general improvement in pernicious anemia resulting from liver treatment there is a return to the normal cholesterol levels and distribution. The rise of the blood cholesterol in pernicious anemia following liver treatment is not necessarily due to the cholesterol in the diet but is more likely due to increased synthesis or to a greater absorption of bile cholesterol. Cell and plasma uric acid and serum calcium show no significant changes in polycythemia vera or in pernicious anemia.

Endocrine Therapy—Aub believes that one should not lay too much stress on endocrine therapy alone. In abnormalities that are largely metabolic in nature, attention to general principles is often of great importance. For example, in obese amenorrheic patients, reduction in weight alone will often be followed by regular menstrual cycles. Removal of foci of

infection will often reduce the intensity of hyperthyroidism. Attention to the factors of general hygiene and metabolism, which formerly were carefully observed in diabetes, are still of value in spite of the great help of insulin. The author stresses these simple principles because they are frequently neglected in modern therapy.

Juvenile Obesity—According to Rony, the juvenile age constitutes a sensitive test period for the detection and identification of glandular disturbances, by virtue of the known marked effects of the glands on somatic, sexual and mental development. He studied fifty unselected cases of obesity in childhood and adolescence for the possible role of endocrine disturbances in the etiology of obesity. Disturbances of the pituitary and sex glands, moderately low basal metabolism without hypothyroidism, abnormal sugar tolerance and mental deficiencies are frequent observations in juvenile obesity. Only six of the fifty cases studied showed no abnormal conditions in at least one of these fields. However, the anomalies found represent deviations from the normal in both directions, since in some cases hypofunction and in others hyperfunction of the same gland was found. This along with other observations strongly suggests that there is a relationship between endocrine anomalies and obesity, but it is not of etiologic nature. The etiology of obesity, juvenile or adult, "exogenous" or "endogenous," is apparently uniform. It is a disturbance of the mechanism that regulates the body fat content and is probably hypothalamic in origin.

Pituitary-Suprarenal-Gonad Relationships—Atwell reports that injection of a potent cortical suprarenal extract (cortin, Hartman) over a period of two months, beginning at 5 months of age, stimulated the ovaries of hypophysectomized tadpoles of *Rana sylvatica*. Such ovaries averaged nearly two and one-half times the size of ovaries from untreated hypophysectomized controls. Twenty rats were hypophysectomized by the parapharyngeal route. Nine of these were injected subcutaneously twice daily with cortin in doses varying from 0.5 to 2 cc for each injection. This treatment partially relieved the characteristic asthenia and hypothermia and partially restored spontaneous activity, without any apparent reparation of the atrophic thyroid, suprarenals or gonads, and without any effect on growth.

Effects of Fever Temperatures on Spirochaeta Pallida—Boak and her associates determined the thermal death time of *Spirochaeta pallida* in extracts from lesions in rabbits' testes in vitro at fever temperature, using the Zinsser-Hopkins and Nichols strains. The criteria to determine the persistence of

infectivity of the heated extract were the following: the development of lesions on inoculation into rabbits, dark field examination of tissue from the lesions, and the outcome of blood Wassermann tests and reinoculation tests. The thermal death time of the two strains of spirochetes was approximately the same, although the Nichols strain was somewhat the more resistant. In the case of the latter, five hours at 39 C (102.2 F), three hours at 40 C (104 F), two hours at 41 C (105.8 F) and one hour at 41.5 C (106.7 F) were required to render infective extracts innocuous to other rabbits. The thermal death time of *Spirochaeta pallida* in testicular extracts in vitro at fever temperatures is so short as to suggest that induced fever may be useful therapeutically in human syphilis.

Fever Treatment in Experimental Syphilis—According to Carpenter and his associates, multiple, unsustained fevers of from 41 to 42 C (105.8 to 107.6 F) produced by irradiation in a high frequency electrostatic field (10,000 kilocycles) destroyed *Spirochaeta pallida* in rabbits with active syphilitic lesions as determined by the injection into normal rabbits of extracts prepared from their testes and popliteal lymph nodes. One febrile period of six hours at a temperature of from 41.5 to 42 C (106.7 to 107.6 F) was likewise found to be sufficient to destroy the spirochetes. Infection with *Spirochaeta pallida* persisted in a control series of untreated rabbits for as long as 395 days after inoculation, but clinical healing occurred in from three to four months after injection. The time interval between inoculation and fever treatment, or between the end of the fever treatment and reinoculation, did not affect the results. The fever treatment was effective at any stage of experimental syphilis in rabbits.

Treatment of Secondary Anemias—Richter and his associates treated 112 patients with secondary anemia due to various causes with 1½ ounces daily of B1 105, a preparation consisting of concentrated whole liver, iron in glycerin and defibrinated blood. An analysis of the preparation showed that 1½ ounces of the preparation contained the extract of 84.4 Gm of whole liver, a total of 104.24 mg of metallic iron (6.75 mg from the liver, 5.62 mg from hemoglobin and 91.87 mg from the neutral glycerin-iron compound) and a total of 1.4 mg of metallic copper. The rationale of the preparation that they used is discussed. A large percentage of their group of patients showed hematologic and clinical improvement on receiving the whole liver-iron preparation and other indicated therapy. The authors state with confidence that the improvement of eleven of the patients can be accounted for primarily on the basis of having received the whole liver-iron preparation. Further evidence as to the effectiveness of this preparation was shown by the drop in hemoglobin and red cells when treatment was discontinued in twenty-one patients representing the various groups previously treated and discharged as normal. Hematologic recovery was obtained when treatment was again instituted under 'home' conditions. Their study has impressed them particularly in regard to the numerous and almost insurmountable difficulties inherent in the problem of determining clinically the value of a therapeutic agent in the hemorrhagic and idiopathic secondary anemias.

Liver Extract in Diabetes Mellitus—Ralli reviews the literature and presents the results she obtained with liver extract in the treatment of thirteen patients with diabetes mellitus. She concludes that in the treatment of diabetes one is always impressed with the ability of the patient to increase his carbohydrate tolerance by adherence to diet and insulin

and if these patients are followed over a period of time the results are, in the majority of cases, striking. This makes it difficult to draw any conclusions as to the effect of a given type of therapy on the course of the disease. In her study the patients were observed for periods of not less than one year and received the extract for never less than five months and in most of the cases for more than five months. Therefore it seems reasonable to conclude that if any improvement was to occur it would have taken place during this prolonged period of observation. In view of this fact one does not feel justified in attributing to liver extract any effect similar to that of insulin on the hyperglycemia or glycosuria of diabetic patients. Her results do not substantiate the observations of Blotner and Murphy. In the young patients observed, neither the dry nor the moist liver extract had any effect on the hyperglycemia, nor was it possible to reduce the insulin requirement during the period of liver therapy. While her observations have been in progress, other investigators have reported a similar lack of effect of liver extract in diabetes.

Intradermal Test for Determination of Malignant Conditions—Gruskin introduces an intradermal test for the determination of malignant conditions, in which 0.2 cc of the antigen is injected intradermally with an extremely fine needle. The injection should not be forced, so that no false pseudopods will be formed. In positive cases, a slight area of inflammation with pseudopod formation appears within fifteen minutes. In negative cases, no such reaction takes place. It is advisable to use a control of physiologic solution of sodium chloride with each test. The control must always be negative, showing no inflammation and no pseudopods. The antigen is made up of purely embryonic tissue obtained from the pancreas and submaxillary glands of embryonic calves, in the case of carcinoma, and of Wharton's jelly and red bone marrow in the case of sarcoma. The author believes that the characteristic embryonic protein is not only carried in the blood stream but also finds response in the fixed cells, as expressed by the allergic reaction. The correct results obtained in a great number of positive and negative cases have been demonstrated, so that he feels justified in publishing this preliminary report. In 116 cases of intradermal tests done on students under the auspices of Fanz, head of the Department of Pathology of Temple University School of Medicine, the following results were obtained. No reactions occurred in 107 students. Eight students gave a slight reaction to carcinoma, and of these one had a maternal history of malignant conditions for three generations, one had a maternal history of malignant conditions for two generations, and six had a family history of malignant conditions for one generation. One student gave a slight reaction to sarcoma and no reaction to carcinoma. He had a paternal history of sarcoma.

Acute Bacterial Endocarditis—Phipps states that acute bacterial endocarditis is in general a fulminating process with a rapidly fatal outcome and, although in many instances the cardiac manifestations may be the most striking, the picture is largely one of an acute sepsis modified by the underlying condition or exciting cause. The author reports forty-four cases of acute bacterial endocarditis in which the sex incidence was thirty-two males and twelve females and the age incidence from 45 to 50 years. *Streptococcus hemolyticus* was responsible for about 50 per cent of the cases and *Staphylococcus aureus* for 25 per cent. The duration was from three days to three weeks. The left side of the heart was more often involved and ordinarily there was a preexisting valve lesion (but so far allergy highly improbable). Treatment should be entirely symptomatic (digitalis, salicylates), and apparent recovery of some cases is rather doubtful, although in the case of meningococcus it is possible.

Attenuation of Measles—Stewart points out that measles is so universally accepted as an inevitable visitation and is commonly so mild that parents are inclined to disregard its possible serious consequences. As 90 per cent of the deaths occur under the age of 5, many lives could be saved if the illness could merely be postponed. Yet under certain conditions measles can also be a menace to adults, as illustrated by the epidemics in training camps during the war. Under conditions of private practice, it is worth while to protect the brothers and sisters of a child with measles by intramuscular injections of blood from some older member of the family who has had measles. This is especially true of the younger children. Unless a child is already seriously ill it is wisest to attempt to produce an attenuated form of the disease, which presumably gives lasting immunity. Whole blood, 20 cc., can easily be injected without delay or complicated equipment. The history that a child has had measles should not be unreservedly relied on.

Liver Kidney Syndrome—Helwig and Schutz describe a syndrome that occurs in adult life and which they believe has not been reported before. In their cases, prior to the appearance of the clinical syndrome, the blood and urinary observations were normal. With its appearance, the abdomen became distended, the pulse increased from 101 to 120, and the temperature rose from 101 to 103 F. The latter observations were soon followed by a progressive oliguria and the appearance of albumin, casts and, often, blood in the urine. Following these changes, the patient usually lapsed into a muttering delirium which rapidly progressed into coma, and the nitrogenous elements of the blood increased while the urinary nitrogen

decreased. At about this time, nausea and vomiting sometimes became prominent symptoms. The latter changes were most marked in the postoperative cases from the fifth to the eighth day when, with the removal of the stitches, a decided delay or even absence of wound healing was observed. Practically always some mucous surface bleeding was noted and in many instances it was so striking that the vomitus and stools consisted almost entirely of blood. The clinical picture then progressed, as a rule, to that of a profound uremia, low grade, generalized edema developed and almost total anuria followed. The retention of nitrogenous products in the blood became more marked and the patients died in a state clinically resembling uremia. At the necropsy examination, generalized edema was almost always present. In all cases the liver showed obvious gross and microscopic damage. The principal gross observations in the kidneys were an increase in size, with obvious parenchymatous degeneration and a notable disappearance of the normal anatomic markings. Submucous hemorrhages were present in the gastro-intestinal tract in almost all cases and free blood was found in the intestinal contents in these instances. Interstitial pulmonary hemorrhages were seen in the majority of cases and other evidences of bleeding, such as petechiae of the skin, hemorrhages from the gums, hemothorax, hemoperitoneum and diffuse submucous hemorrhages in the renal pelvis, were found. All the gallbladders that were removed at operation showed evidence of long standing inflammation and the liver tissue adjacent to these gallbladders presented, in all instances, the most marked degree of hepatitis. The authors present six cases illustrating the clinical and pathologic hepatorenal syndrome. Their animal experiments tend to substantiate this pathologic relationship. They advance the hypothesis that damaged liver tissue elaborates some potent toxin which acts more or less specifically on the kidneys.

Tumors of Appendix—Norment found 67 cases of carcinoma in a study of 45,000 appendices, the average age of the patients was 38 years, and 67 per cent of the cases occurred in females. One venous hemangioma of the appendix was found. The presence of pseudomucin in cystic appendices, rather than mucin, was demonstrated by mucicarmine and safranin stains and chemically by Hammarsten's reduction method. The author emphasizes the absence of definite symptoms or laboratory evidence of tumors of the appendix. In his series he found that the chief complaint of twenty-eight patients was pain in the right lower abdominal quadrant. In the remaining cases the pain was in reference to associated pathologic conditions. The chief complaints of patients with cystic appendices were pain in the right lower abdominal quadrant in thirteen cases, pain in the epigastrium in seventeen and pain over the gallbladder in five. A history of carcinoma in the family was found in nine cases, and of carcinoma of the appendix in one case. Among patients with cystic appendices, carcinoma had occurred in the families of four and tuberculosis in one.

Effect of Roentgen Rays on Ovaries—Drips and Ford had difficulty in securing uniform destruction of functioning ovarian structures with any one exposure to roentgen rays, owing partly to individual variations in sensitivity of the follicles in different animals and partly to technical difficulties of securing uniform radiation limited to the ovarian field. A certain proportion of small follicles and primary oocytes apparently is uninjured even by the most intensive radiation used (just within lethal limits) and cyclic activity of the uterus continues during the time of their development although the animals are usually not fertile except for a brief period immediately after irradiation. The results of irradiation in their experiments confirm the fact that with complete atrophy of all functioning structures no cyclic activity occurs. This is apparently not in accordance with the observations of Parkes and of von Schubert, both of whom have reported a continuation of the estrual cycle after all the follicular structures in the ovaries of mice had been destroyed by irradiation. A peculiar hyperplastic structure has been discovered in the ovaries of rats killed late after exposure to roentgen rays, and in these rats a late return of the estrual cycle apparently occurs.

Treatment of Carcinoma of Rectosigmoid—Without in the least comprising the radical features of the operation Babcock modified the conventional abdominoperineal operation

in four ways 1 The colostomy is eliminated, thus saving time and reducing the danger of peritoneal contamination. An immediate peritoneal anus is produced without clamping, division or suture of the intestine within the abdominal cavity. To avoid infection, the intestine is not opened or removed until all wounds are closed and the perineal dressings are in place. At the close of the operation, a rectal tube is tied in. Thus the dangers of an obstruction colostomy are avoided and, as a rule, there is little secondary postoperative abdominal distention, the early passage of gas being facilitated. 2 No pelvic diaphragm is formed. By this omission time is saved, complications are avoided, and the postoperative disability from the slow obliteration of the large pelvic cavity is reduced. The open and drained pelvic cavity, although denuded, rarely causes intestinal obstruction. It is the author's impression that patients make better postoperative progress without the peritoneal diaphragm. Therefore he does not hesitate to do a radical resection of the peritoneum with no attempt at peritonealization. 3 A safe "pull through" method is used. The diseased intestine is brought through the pelvic floor, but traction is made only through the healthy intestine. A band of soft gauze about 2 inches wide is tied about the sigmoid well above the carcinoma. The ends of this gauze are packed against the pelvic floor, where they may easily be located and withdrawn through a perineal incision after the abdomen has been closed. The gauze tie also indicates the site for the perineal anus. 4 A perineal colostomy or anus is immediately formed. The discredit that has attached to the sacral or perineal anus has been due, he believes, to the technic and the poor viability of the intestine used. In many of the older operations, the end brought to the perineum sloughed for some distance into the pelvic cavity and left a cicatricial opening that was the source of much later trouble. When the blood supply to the segment of sigmoid brought through the perineum is preserved, necrosis does not occur and an opening of ample size with little tendency toward a secondary stricture is readily formed.

Surgical Correction of Uterine Displacements—Wollner's modification of the Gilliam operation is as follows. The abdomen is opened by a small midline incision extending downward to a point directly above the pubis. The fascia and peritoneum are incised in the linea alba. The patient is placed in the Trendelenburg position and the intestine pushed upward. The uterus is brought forward into the correct position and both round ligaments are grasped with clamps. A small opening is made in the fascia on each side and a clamp is pushed through the muscular layer and peritoneum. The round ligament is brought through the newly formed canal and is fixed to the outer surface of the fascia, two silkworm-gut sutures are used on each side. The round ligament is not shortened, only a small loop being fixed above the fascia. The author briefly reports 100 cases in which he used this operation. He concludes that it should not be performed as a routine measure but modified according to the indications in each individual case. He recommends the use of silkworm-gut ligatures to obtain permanent fixation. The relation of sterility and habitual abortion to retrodisplacement of the uterus is problematic. The existence of either of these conditions should not be considered as an indication for ventral suspension. The surgical correction of retrodisplacement is an elective procedure. Since operation does not result in the alleviation of all symptoms in every case, the patient should be informed to that effect before the operation.

Rheumatic Pericarditis—Cook reports the great frequency with which pulmonary signs are found in association with acute rheumatic pericarditis. The pulmonary signs occur much more frequently on the left side than on the right. The pulmonary condition may occur quite apart from a pleural or pericardial effusion. Both the severity of the signs and symptoms and their duration show considerable variation. The histologic appearance of the lungs is one of collapse and passive congestion rather than that of a specific inflammatory condition. The view is put forward that the pulmonary condition may be regarded as an active massive collapse of a portion of the lung due to reflex disturbance of the vagus and sympathetic innervation of the lung from inflammation of the pericardium.

Epithelioidosis—Cameron states that the existence of benign infiltration remains to be proved. It can be demonstrated only by the accident of an opportunity being afforded to perform a necropsy during the time when the extensive consolidation is present. The finding of caseous consolidation in a

case thought to be one of benign infiltration, or the finding of tubercle bacilli in puncture of the lung, proves only the difficulty of diagnosis. Even if one accepts the view that the prognosis in true tuberculous consolidation of the lung is less grave than has been assumed in the past and admits that even young children will at times tolerate such an extensive lesion well and make at least a partial recovery, surviving for many years, nevertheless the almost invariable recovery in typical cases, the absence of any constitutional symptoms, the regular outline and localization of the shadow, its appearance in some cases after tuberculin injection, and its occasional rapid disappearance in others make it difficult to believe that this consolidation is due to replacement and destruction of the alveolar tissue of the lung by a caseous process. The author reports a case of the rapid disappearance of a large and persistent shadow.

Urea Tests of Kidney Function—Poulton and Ryffel draw attention to the fact that the urea concentration test is unreliable and should never be used. The urea output test is a good rough test of kidney function, 15 Gm of urea should be given in about half a pint of water in the morning without breakfast and the maximum output calculated during the following three hours. The authors give the minimum normal figures. It is safer to make sure previously that the blood urea is within normal limits, and in these circumstances the accuracy of the test depends on the blood urea rising to about the same height, this is usually, but not invariably, the case. For accurate work the standard or maximum blood urea clearance test should be used, the calculation of standard or maximum clearance must be made according as the hourly volume falls below or above 2 cc a minute, the maximum clearance test, though more elaborate, is probably the more accurate of the two. There is a tendency for the maximum blood urea clearance to fall off in successive hours. In nephrosis the excretory function of the kidney for urea is usually depressed, in some cases of hyperpiesia the maximum clearance is normal, which suggests that the origin of hyperpiesia may be independent of renal disease.

Bacillus Coli Infections—Ryle believes that the colon bacillus may enter the circulation in certain constitutional types and as a result of certain well recognized disposing causes. A transient bacillema results and is followed by pyelitis and cystitis, or by cholecystitis during the excretion of organisms by way of the urinary and biliary tracts. Orchitis and prostatitis are rarer sequels. Late residual infection of the renal pelvis and bladder or of the gallbladder and ducts is common. Adequate treatment with full alkalization gives satisfactory results in the early stages of the urinary infections. The treatment of chronic bacilluria is unsatisfactory, but it may be improved by the new method of giving ketogenic diets. Morning salts and disinfection with methenamine are effective in the early and milder infections of the biliary tract. In a minority of both the renal and the biliary cases medical treatment is rendered unavailing by an added obstructive or mechanical factor, the presence of which can often be appreciated by a careful attention to historical detail and symptoms. Surgical treatment is appropriate in these cases. A wider appreciation of the importance of a healthy intestine and the avoidance of the purgative habit would probably do more to diminish the incidence of these prevalent infections than any other single measure.

Thrombophlebitis Migrans—Hartfall and Armitage report in detail two cases of thrombophlebitis migrans, one with typical lesions in the superficial veins of all four limbs and visceral lesions affecting the pulmonary, the coronary and, probably, the mesenteric vessels, the other of a more local migratory type without visceral lesions, being limited to the superficial and deep veins of the legs and their tributaries. In both there were active sources of focal sepsis, which were considered to be of importance etiologically and which were treated. Although clinically there was nothing to suggest any relationship to thrombo-angitis obliterans, examination of a vein obtained by biopsy in the first case showed certain histologic resemblances to changes described in the veins in that condition. The local change in the wall of the vein appears to be primarily a chronic, and presumably recurring, endophlebitis having a special localization in and around the valve cusps, and thrombosis occurs especially in these situations.

Anemia of Lederer—O'Donoghue and Wits present four cases of the acute hemolytic anemia of Lederer collected from the Guy's Hospital records, three of which have already been published in Guy's Reports by Barford and Shackle, and one of which is new. An additional thirty-two cases have been collected from the literature and a general picture of the disease has been drawn from all these cases. The disease is characterized by pyrexia, anemia of the hemolytic type with reticulocytosis and hyperbilirubinemia, and a relatively brief duration, megalocytosis is not present. Hemoglobinuria is present in the more acute cases. Leukocytosis is usual, and often the blood picture simulates acute leukemia. The untreated disease has a high mortality, but treatment by transfusion is usually curative. The acute hemolytic anemia of Lederer appears to be a specific illness due to infection, but the nature of the infection is unknown.

 *Duodenal Ulceration in Infants Account of Two Cases C F Brockington and R Lightwood—p 1209
 *Autogenous Urinary Proteose in Rheumatoid Arthritis G R P Aldred Brown and J M H Munro—p 1211

Addisonian Anemia Following Gastrectomy—Rowlands and Simpson give an account of fifteen cases, from the literature, of addisonian anemia following gastrectomy or gastrojejunostomy and tabulate their special features. To these are added two cases of addisonian anemia showing subacute combined degeneration following partial gastrectomy for simple ulcer and carcinoma, respectively. The authors discuss evidence of the association between the operation and the subsequent anemia. They conclude that the sum total of evidence suggests that the occurrence of primary anemia after gastric operations is not a mere coincidence.

Duodenal Ulceration in Infants—Brockington and Lightwood give the case reports of two infants, aged 10 and 2 weeks, respectively, who died of duodenal ulceration. The clinical picture resembled that of other cases (about 200) recorded in the literature, namely, failure to thrive, and vomiting and pain after food. Melena or hematemesis seem to occur in about half the cases, and diarrhea also in about half. The infants are always wasted and they are rarely above 5 months of age. The diagnosis is one of great difficulty during life, 160 or more of the 200 recorded cases have been recognized in the postmortem room. There is reason to suppose that the diagnosis should be made more frequently, and it is suggested that it should be considered in all infants below the age of 5 months who are declining in a state of atrophy. The prognosis is poor, death usually results from inanition, occasionally by perforation (eleven recorded instances) or by massive hemorrhage. The pathology of the condition is that of a single or multiple ulceration, always lying on the posterior wall of the duodenum between the pylorus and the ampulla of Vater. The pathogenesis is in doubt, the authors consider various hypotheses.

Urinary Proteose in Rheumatoid Arthritis—Aldred Brown and Munro selected fifty cases of true active rheumatoid arthritis and prepared autogenous urinary proteose vaccines. Adopting the usual standard for positive skin reactions, they found that all the patients treated were consistently negative to intradermal, scratch and patch reactions (with one exception in the latter group). Some points in the preparation of the proteose are considered, and the question is discussed whether the substance isolated is of a proteose nature. Inquiry was made into the patients' previous and family history with regard to allergy. The following facts were elicited: (1) previous history of allergy, 4 per cent, (2) family history of allergy, 2 per cent, (a) previous history of rheumatic fever, 8 per cent, (b) family history of "rheumatism" (all forms), 26 per cent. Attempts were made by treating patients over long periods with various doses and at various time intervals with the proteose to produce amelioration, but in only one instance was any apparent success obtained. From this the authors draw two conclusions: 1. Autogenous urinary proteose does not produce skin reactions in rheumatoid arthritis similar

to those produced by antigens in cases of allergy, further, its toxicity in rheumatoid arthritis has been exaggerated. 2 As a therapeutic agent in the treatment of rheumatoid arthritis, urinary protease appears to be useless

- Principles Governing Prognosis in Heart Disease. L. E. Hurley—p 677
 *Notes on Use of Paraldehyde as Basal Anesthetic. J. L. Thompson and L. J. T. Hartnett.—p 682
 Note on Macroscopic Anatomy of Nerves of Bladder. A. E. Coates—p 683
 Congenital Intestinal Occlusion Report on Five Cases. G. K. Smith—p 685
 *Deliberate Opening of Bones as Treatment for Rheumatoid Arthritis. J. F. Mackenzie—p 690

Paraldehyde as Basal Anesthetic—Thompson and Hartnett state that the advantages of paraldehyde over other basal anesthetics which have come under their notice are as follows 1 The drug is easily handled and its mixture with physiologic solution of sodium chloride calls for nothing more than ordinary care. 2 The administration can be safely entrusted to a nurse and does not make any undue call on the time of the anesthetist 3 The certainty of its action has been one of the features in their series of cases 4 The dose necessary to produce the desired effect falls far below the minimum recorded fatal dose 5 While it is necessary to give ether by the open method to bring about surgical anesthesia, the amount required for and the time occupied in induction are greatly lessened 6 A small amount of ether is required to maintain the necessary depth of anesthesia, and it is easy to bring about full muscular relaxation when this is required. 7 Diminution of shock was manifest as compared with ordinary methods of anesthetization 8 The postoperative discomfort was lessened so much that there was no nausea, vomiting or pain in the majority of cases 9 There was no recollection of any of the preparations preliminary to operation 10 Most important in a large general hospital is the trifling cost of inducing and maintaining unconsciousness

Opening of Bones in Treatment of Rheumatoid Arthritis—Mackenzie states that the making of openings in some of the large bones has a curative effect on the condition known as rheumatoid arthritis. In the nineteen operations done, rarefaction of bone has been noted, accompanied by undoubted evidence of decalcification, with a marked fatty degeneration of the bone marrow, which flows like thin motor oil from the openings made in the bone. The earlier the case, the less thin the oil is found to be. The bones chosen by the author for opening are the femur and the tibia. Both legs are operated on, the lower end of the femur on the anterolateral aspect being the most convenient site and the upper end of the tibia on the anteromedian aspect being selected. Three-fourths inch trephine openings are made and sometimes enlarged. A preliminary report of this method of treatment was published by the author in the *Medical Journal of Australia* April 11, 1931. Manifestations of the curative effect are 1 Relief of pain 2 Improvement in the well being of the patient, manifested by a most striking improvement in the red cell count. An increase of 100,000 per cubic millimeter in a fortnight is common and usual, an increase up to 700,000 in that time has been noted, in one case an increase of 1,000,000 in one month was found 3 Improved functioning of the limbs, probably due to the relief from pain which previously accompanied any movement

- *Erythema Multiforme Infectious Disease or Intolerance Reaction. A. Tzanck and M. Cord—p 1073

Erythema Multiforme—Tzanck and Cord think that two essentially different diseases are mistakenly grouped together under that name: one an infectious disease of undetermined etiology, the other a reaction of intolerance to a large variety of agents. The onset of the infectious form is marked by the appearance of slight fever, malaise, lassitude and rheumatoid pains from four to seven days before the eruption, these general symptoms recede gradually after the appearance of the eruption. There is usually a slight leukocytosis but no eosinophilia. The evolution of the erythema lasts about two weeks. This form is linked to a severe, pyretic form by many intermediate forms. In the erythema multiforme which is an intolerance reaction, the character, localization and manner of appearance of the eruption are identical to that of the infectious form, but there are several characteristics which differentiate it from the latter. The most constant and easily determined symptom which differentiates the erythema of intolerance from the infectious erythema is a marked pruritus. Other distinguishing characteristics are: absence of an initial infectious phase, eosinophilia without leukocytosis, anamnesis of asthma, hay fever, eczema or urticaria, demonstrable sensitivity to an antigen, and a multiplicity of causative agents: chemical (albuminoid or crystalloid) or physical (light or heat). The differentiation between infectious erythema multiforme and the erythema multiforme of intolerance is important from a therapeutic as well as a theoretical point of view, as the former should receive antinfectious treatment and the latter should be treated by desensitization.

Rickets in Presence of Calcium-Fixing Agents—Mouriquand and his associates studied the effect of various calcium-fixing agents on a group of thirty-four children with rickets, who were hospitalized under good hygienic conditions but without sunlight. Most of the children were hypotrophic, a few were in good condition. The authors found that the direct action of ultraviolet rays has by far the strongest calcium-fixing powers. Irradiated sterols are powerful calcium fixing agents but are inferior to direct ultraviolet irradiation, the latter is sometimes efficacious in cases resistant to irradiated sterols. Epinephrine was found to have no antirachitic power, and the calcium-fixing action of cod liver oil was found to be very feeble. However, there are cases of rickets that are resistant to ultraviolet irradiation, the authors call them "uvioresistant." The uvioresistant cases are found chiefly among the hypotrophic forms and especially among those which, roentgenologically, exhibit a streaked condition of the bones, an osteoporosis of the diaphyses, periostitis and fractures. The authors think that in uvioresistant cases of rickets one may try antisiphilitic treatment, as the other factors producing that condition are still unknown.

 Verne's Resorcinol Reaction in Cerebrospinal Fluid in Tuberculous Meningitis. M. J. Caussimon—p 20

Search for Tubercle Bacilli in Gastric Contents—Pichaud and Bacquet state that the examination of gastric contents for tubercle bacilli is a valuable aid for the diagnosis of incipient or latent forms of tuberculosis without expectoration in the adult as well as in the child. While pulmonary tuberculosis in its earliest stage is usually a lesion which does not communicate with the bronchial passage, the tubercle bacilli soon pass to the exterior but are usually swallowed because there is no expulsive cough. The authors' opinion is

based on their experience at a clinic for patients suspected of incipient or latent tuberculosis, or having pseudotuberculous respiratory disturbances, pithiatism or other diseases in which tuberculosis is to be ruled out. Gastric lavage is practiced systematically at the clinic. It is performed in the morning on the fasting patient by means of an Einhorn tube, through which from 40 to 80 cc of water is introduced and then aspirated. The fluid is centrifugated and the sediment of each tube is suspended in 30 cc of water, treated with ten drops of caustic soda and heated for ten minutes. It is then recentrifugated for forty-five minutes and the new sediment is poured on a slide without spreading and stained by the Ziehl-Neelsen method. The scarcity of the bacilli demands careful and complete examination of the slide made from each centrifuge tube. Thus examination is considered a sufficient guarantee for the presence or absence of acid-fast bacilli. In rare cases of persistent doubt in the presence of a negative result, a guinea-pig may be inoculated.

*Familial Adiposogenital Dystrophy and Cranial Defects T Lucherini—p 53

Familial Adiposogenital Dystrophy and Cranial Defects—Lucherini made a study of a man, aged 21, his brother and his sister, who all presented familial adiposogenital dystrophy of Froehlich's type, accompanied by cranial defects of the same type. Roentgen examination revealed in all some evidence of acromegaly and thickening of the bony shell of the frontal region, with areas of greater transparency, pronounced depressions for the diploic canals and a marked depression of the occipital fossa. The markings on the bones caused by the cerebral convolutions were especially apparent on the frontal bone. There were small erosions of the inner table of the cranium. In the lateral aspects there were exaggerations of the lacunar diploic system. The sigmoid or the transverse sinus was prominent behind the solid part of the petrous portion of the temporal bone. The author maintains that the dystrophy did not follow a lesion of the pituitary body but was the result of some obscure primary or secondary lesion of hypothalamic nerve centers. This coincides with the modern concept of a diencephalohypophyseal genesis of the disease. All three patients had a positive Wassermann reaction, the infection presumably coming from the paternal side. Thus the author deems important in the causation of the neurohypophyseal and cranial syndromes. The osseous alterations of the cranium together with the general clinical symptomatology made possible a diagnosis of endocranial hypertension and suggested the idea of an osteodystrophy of probable endocrinopathic origin. The author finds these cases interesting from the standpoint of roentgenology and also because of the light they throw on the still unclarified neurohypophyseal clinical syndrome.

Exciting Cause of Appendicitis and of Postappendicular Peritonitis—Gundel of the Hygienic Institute of the University of Heidelberg studied 167 cases of acute appendicitis, appendicular abscess and peritonitis of appendicular origin, with the view of determining the exciting cause of acute appendicitis. Extensive bacteriologic, blood culture and histologic studies were made in each case. A throat smear and a bacteriologic study of the blood and feces were made in most cases. With a single exception, the blood cultures proved negative, suggesting that acute appendicitis is not a blood-borne infection. No constant relationship was observed between the throat and the

bacterial flora of the appendix. It was demonstrated that, besides the normal inhabitants of the oval cavity, there existed a variety of micro-organisms capable of passing into the intestinal canal and becoming part of the normal intestinal flora. In seven cases the bacterial flora of the throat and the appendix was identical. This was true of hemolytic streptococci and of pneumococci. Further serologic type differentiation of the pneumococcus demonstrated in each case an homologous type in the oral cavity and in the appendix, establishing for the first time the possibility of passage of microbes alien to the intestinal tract from the mouth to the appendix. The same organisms were recovered from the feces. The author emphasizes the importance of histologic studies of appendixes as originally introduced by Aschoff. These, supported by careful bacteriologic studies, enabled him to conclude that the enterococci, with the related nonhemolytic streptococci, are the causative factors of acute appendicitis. In a small percentage, other organisms, such as the hemolytic streptococcus, the bacillus of Friedländer and the influenza bacillus, were responsible. The specificity of enterococci is suggested by their localization, their regular occurrence in the deeper tissues of the appendix and the presence of phagocytosis of the finer gram-positive micro-organisms of the enterococcus and the related groups. The larger gram-positive organisms characteristic of fecal flora were not observed in such tissues. Quite to the contrary were the conditions in the case of appendicular abscess or of appendicular peritonitis. Here the original exciting micro-organisms disappear and the bacteria of the fecal flora become predominant. The most important among these are the colon bacillus and the gas bacillus. The exact role of the latter in the free peritoneal cavity is not clearly understood. The important part in the morbid process is probably played by the colon bacillus. It appears that the initial inflammatory process prepares the way for the micro-organisms of the fecal flora. After the perforation, the original organisms of the enterostreptococcus group recede into the background and the colon bacilli come to dominate the morbid process.

Adhesions of Large Intestine—Fenkner is opposed to the conception, prevalent among surgeons and reflected in the extensive reports of Nordmann (1926) and of Finsterer (1930), that phlegmon of the large intestine is a rare and an almost always fatal condition. He believes, to the contrary, that the condition is much more common than is generally believed, that it is frequently mild, and that it passes on to healing without surgical intervention. He reports, from his own material, fourteen cases of phlegmonous inflammation involving one or the other segment of the large intestine. These cases did not include inflammations of the vermiform appendix. The significance of such inflammatory states is that they lead to formation of adhesions capable of giving rise to symptoms at a later date. Such adhesions and membranes were always believed to be of congenital origin. The author points out that while adhesions are found in about 4 per cent of the new-born, their incidence is much greater in later life. The author believes that congenital membranes or adhesions do not, as a rule, cause symptoms. Such adhesions as cause symptoms are of inflammatory origin and should be submitted to surgical treatment. These adhesions are typical for the large intestine. They resemble considerably adhesions about the pylorus and stomach the origin of which is likewise of inflammatory nature.

Determination of Pancreatic Ferment—Bauer points out the relationship between the diseases of the biliary tract and the pancreas and the desirability for a reliable functional test of damage to pancreatic tissue. In eighty cases of acute or subacute disease of the pancreas, 25 per cent were cases of primary pancreatitis, while 97.5 per cent were secondary to disease of the gallbladder and the bile ducts. In 78.8 per cent gallstones were present, while 18.7 per cent were cases of cholecystitis without stones. Wohlgemuth's urine diastase test gave a wrong indication in five out of ninety-eight negative tests. Three of these were proved at operation to be cases of chronic pancreatitis, and two proved to be cancer of the pancreas. Out of seven cases giving a positive Wohlgemuth test, five exhibited at operation pathologic lesions in the pancreas, while two cases presented stones in the common duct without, however, showing changes in the pancreas. The author, therefore, concluded that increased diastase in the urine is not necessarily pathognomonic of a disease of the pancreas. A negative test suggests the absence

of an acute process in the pancreas. In a group of 100 patients with gallbladder disease, the blood serum was investigated for pancreatic lipase after the method of Rona. In eighty-nine patients whose pancreas was demonstrated at operation to be normal, the difference in the number of drops required to split tributyrin solution with atoxyl and tributyrin solution without atoxyl was four drops after ninety minutes. A higher number than four drops was considered abnormal and indicated a difference in surface tension of the tributyrin solution brought about by the action of a pancreatic lipase which, alone of all fat splitting ferments found in the blood, is capable of splitting fat even in the presence of a poison such as atoxyl. In eleven cases of acute or chronic disease of the pancreas, as demonstrated at operation, the Rona test gave a difference of from five to sixteen drops. Both the positive and the negative tests gave a correct indication in all the cases. The author concludes that the Rona test is a more sensitive and more accurate test of early pancreatic damage, in conjunction with bile tract disease, than the Wohlgemuth test.

Anesthesia of Phrenic Nerve as Test Operation.—It is pointed out by Hein that the phrenic operations, the permanent as well as the temporary exclusions, involve uncertainties, since it cannot be known before the intervention how high the diaphragm will go. In order to be able to determine this in advance he resorted to anesthetization of the phrenic nerve by means of a 0.5 per cent solution of procaine hydrochloride. He describes the technic of this intervention and shows that it is simple and harmless. Exposure of the nerve is not necessary for it can be reached with the simple anesthesia cannula. The anesthesia takes effect immediately and persists for from 30 to 120 minutes. During this time the position of the diaphragm is verified by roentgenologic examinations. The author considers the temporary paralysis of the phrenic nerve a test operation and states that he never followed it immediately by the operation but first studied its effect on the lungs and on the entire organism particularly the circulation.

Control of Cough.—According to Lohfeldt coughing not only is a periodic disorder, to which any one may be temporarily subject but also concurs with some chronic diseases in that it intensifies them or is the symptom that causes the disorder to be troublesome. Chronic bronchitis, for instance, would be bearable if it were not for the annoying cough. In many laryngeal catarrhs the patient becomes conscious of the disturbance by his continued coughing and 'clearing of the throat'. In cases of tuberculosis coughing may actually endanger the life of the patient because it prevents him from having the proper rest. Asthma is likewise exacerbated by coughing. Thus it is evident that rational and effective control of coughing is in many cases of primary importance. This can sometimes be accomplished by the use of expectorants but in some cases they are not effective and the cough has to be counteracted by control of the laryngeal function. The aim should be to limit the cough to the few hawks that are really necessary for many patients make the mistake of coughing too much. The author describes the mechanism of coughing and shows how it can be controlled. The process of coughing consists in an air tight closure of the larynx and an explosive opening. Thus coughing can be controlled by preventing closure of the larynx or by preventing an explosive opening. The first can be accomplished by letting the patient form a toneless friction sound such as a toneless S whenever irritation is only slight. If the irritation is more severe the coughing reflex can be counteracted by the stronger respiratory and opening reflex by short rapid breaths so that the larynx finds no time for closure. Coughing can also be prevented by inhibiting the

explosive opening of the larynx after closure has taken place. The air-tight closure is opposed by a strong air pressure, this is "suppression" of coughing, a mechanism that many persons develop unconsciously by suppressing a cough, for instance, in a theater. After a short suppression the irritation usually recedes, but if it still persists the closure can be broken by a few short breaths. The author also shows that, in patients with laryngeal and respiratory disorders, clearing of the throat may be even more harmful than coughing, in that it irritates the larynx without accomplishing the elimination of accumulated mucus. However, clearing of the throat can also be done in a way that accomplishes elimination of the mucus and yet does not injure the larynx. This is done best by advising the patient to exhale and inhibit exhalation by air-tight closure of the vocal cords. He must have the feeling that a slight increase in pressure is sufficient to force the air through, and this should be done by letting a little air escape first and then follow this by a stronger air stream.

Ileus During Puerperium.—Liebmann points out that ileus is comparatively rare during the puerperal period because in the course of ten years only two cases were observed among 16,151 deliveries. He describes the clinical histories of these cases and gives his theory of the pathogenesis in each case. The recognition of extragenital abdominal disorders, ileus among them, is extremely difficult during the puerperal period, because pains, spasms and sensitivity are usually thought to originate in the genital organs. Thus the correct diagnosis may be made too late. Therefore, the author advises that, whenever vomiting, constipation and meteorism occur simultaneously during any phase of the puerperium, the possibility of an ileus should be taken into consideration, otherwise the opportune time for an operative intervention may be missed.

Treatment of Bed-Wetting.—By considering nocturnal enuresis together with the other symptoms of nervous irritability, which the anamnesis generally revealed, Nelken decided to try sedative treatment. He found bromides ineffective but obtained favorable results with calcium chloride. He administered the calcium in comparative large doses. Three times each day, before meals, the children were given in fruit juice one-half teaspoonful of a mixture consisting of calcium chloride 50 Gm, acacia 5 Gm, and water to make 100 Gm. After a few days, or at least after two weeks, of this medication the nocturnal enuresis ceased. However, the success was not always final. During colds the enuresis sometimes returned temporarily and the author advises the continuance of the medication for several weeks beyond the time of the first effectiveness. Other good results of the calcium treatment were an improvement in the appetite, a deeper and more restful sleep, and particularly a disappearance of the nocturnal gnashing of teeth and of accompanying symptoms. Thus it is evident that the calcium therapy decreased the irritability. The calcium therapy was also effective in pollakiuria during the day and in dribbling of urine. Of course in cases of bed-wetting that are the result of a wrong diet or of a lack of proper training, calcium therapy is not indicated, for the treatment with calcium means the treatment of the irritable child in whom nocturnal enuresis is only a partial symptom.

Acute Pulmonary Edema in Mitral Stenosis.—Schellong's report indicates that mitral stenosis has a special position among the valvular defects of the heart. This unique position is the result of peculiar processes in the lesser circulation because mitral stenosis cannot be compensated within the lesser circulation. Certain interrelations between the systemic circulation, the heart and the lesser circulation give mitral stenosis a special clinical character. This is produced by acute increase in the blood supply of the already congested lung which in turn is the result of increased venous afflux to

the well functioning right heart, while the outflow from the lung is not equal to this. The mobilization of blood from the periphery seems to be especially easy in some cases of mitral stenosis, because it seems to be produced by conditions that in normal persons do not in the least affect the circulating quantity of blood. Moreover, a too strong digitalization may also increase the afflux to the lung. The careful observer will grasp the significance of symptoms that otherwise may seem unimportant, such as a short dyspnea produced by slight somatic or psychic causes, palpitation of the heart, backache and psychic manifestations, such as depression and restlessness. If afflux and discharge do not become adjusted soon, for instance during the night, following exertion or after digitalization, cardiac asthma and pulmonary edema may develop. Efficient functioning of the right heart is required for all these conditions. If this function becomes impaired, decompensation of the systemic circulation with swelling of the liver and with edema sets in. Thus decompensation of the right heart usually develops slowly in mitral stenosis as in other valvular lesions, but in acute pulmonary edema it may develop rapidly, particularly if the right ventricle previously was already at the limit of its capacity. An understanding of the pathogenesis is of the greatest significance in the treatment. In patients in whom a pulmonary edema threatens or has already developed, the author advises against the use of strophanthin because, if the right ventricle functions properly, there is no need for it and it can only be harmful, and, if an insufficiency of the right heart develops with swelling of the liver and edema, the right heart decreases the afflux of blood even without the aid of strophanthin. Attention is called to the prompt action of venesection and to the importance of the intravenous injection of vasodilatory agents in order to fill the empty blood depots. Preparations that have a vasoconstrictory effect are contraindicated. Oxygen inhalation is of great value in mitral stenosis just as in other forms of pulmonary edema. If pulmonary edema develops following medication with large doses of digitalis, medication with digitalis or even with strophanthin should be discontinued and vasodilatory agents should be employed. If digitalis action is necessary for preserving the equilibrium between the lesser and the systemic circulations, digitalis substitutes may prove helpful.

Bacillemia and Bacilluria in Tuberculosis—Deist thinks that the rarity of a positive blood culture in tuberculosis is not the result of an unsuitable culture medium but of the fact that the blood cannot be examined often enough. For this reason bacilluria has been given more attention recently because, if tubercle bacilli are found in the urine and a tuberculosis of the urinary and genital organs can be excluded, they can originate only in the blood, and thus bacilluria is an indirect proof of bacillemia. The author examined the urine of thirty-one patients on twenty-five successive days. The urine of twelve patients contained tubercle bacilli and, with one exception, their sputum likewise contained tubercle bacilli. However, the bacilluria was not constant. In most of the patients the bacilli were found in the urine only on one day, in two patients on four days and in two others on two and three days, respectively. It is also noteworthy that, with one exception, the twelve patients had undergone several surgical interventions. The demonstration of tubercle bacilli in the urine was possible in seven cases immediately after a surgical treatment, such as the making or refilling of a pneumothorax, a thoracocautic intervention or an interruption of pregnancy. The author emphasizes that, in all of the twelve patients in whom bacilluria was demonstrable, a tuberculous involvement of the urinary and genital organs could be excluded.

Irritation Wheal—Sippy and Stejskal direct attention to an irritation therapy of pain. Reports in the literature, particularly Goldscheider's investigations on the mechanism of the pathogenesis of pain and on the efficacy of counterirritation,

induced them to search for a substance that would stimulate the temperature nerves to produce a burning sensation but would cause only slight pain when a wheal was produced with it. They found the following combination to be the most suitable: tincture of capsicum 1, phenol 0.05, urea 20, and spirit of mustard 78.95, but they state that this dosage is only approximate and that they used a solution that was prepared for them by a pharmaceutical house. The tincture of capsicum is probably the most important constituent, since it stimulates the temperature nerves. The phenol is supposed to have an antiseptic effect, and the hypertonic concentration of the solution, which is produced by urea, is to prolong the irritation. The authors observed that in normal persons this solution, if administered intracutaneously, produces a hyperalgesia of the surrounding tissues, particularly centrally, and also in the underlying muscles. The wheal, a hemorrhagic papule on the skin, disappears in about ten days. If the solution is given to counteract pain, it is administered at the site of spontaneous hyperalgesia. The authors tried treatment with the irritation wheal on about seventy patients with various disturbances, such as febrile acute articular rheumatism, subacute arthritis, pains in the knees or shoulders, renal calculi, pleurisy, esophageal disorders, angina pectoris, gastric crisis and muscular spasms. After discussing the mechanism of the treatment, the authors conclude their report by stating that their main object was to call attention to their efforts and to encourage further work in this direction.

Abnormally Long Duration of Pregnancy—Tausch states that the normal length of gestation is usually considered to be 273 days from the date of conception or 280 days from the date of the last menstruation. However, he considers as abnormally long only those terms that exceed 302 days (273 plus 28 plus 1), because conception may have taken place late in the intermenstrual period. This could prolong gestation 28 days over the 273 days and 1 day for delivery, particularly in women whose menstrual intervals are longer than 28 days. He cites statistics showing that a prolongation of the gestation period beyond 280 days, but not in excess of 302 days, occurs in a considerable percentage of cases. A gestation period of more than 302 days is rare but, after citing ten cases from the literature in which pregnancy lasted from 334 to 376 days, the author describes a case of his own observation in which delivery was artificially induced 343 days after the last menstrual period. The woman, aged 27, was a primipara. Her anamnesis revealed nothing unusual except that her mother was reported to have carried about three weeks over the normal term in all of her thirteen pregnancies. After labor had been induced in the primipara by means of pituitary extract and by other measures, the delivery was spontaneous. The infant, a well developed girl, was alive and was considerably larger than the normal child. It was 56 cm. long and weighed 5,000 Gm. The author discusses the causes of prolonged pregnancy and points out that the problem of abnormal length of gestation, besides having biologic and obstetric significance, is also important in forensic medicine.

Blood Transfusion in Puerperal Sepsis and in Secondary Anemia—Kochmann shows that an etiologic therapy of puerperal sepsis has not been found as yet and that most of the pharmacologic and serologic treatments have accomplished little or nothing. For this reason he resorted to blood transfusion but, to guard against self delusion about its efficacy, he employed it only in severe cases. The reports in the literature differ widely in their evaluation of blood transfusion in puerperal sepsis but, since its harmlessness was proved, the author decided to try it, with the following points in view: 1. Puerperal sepsis frequently develops following severe loss of blood, and transfusion makes up for this loss at least temporarily. 2. Transfusion compensates at least partially for the deficient formation of antitoxic and antibacterial substances. 3. The circulation is usually impaired, and transfusion fills the circu-

latory system with a biologically valuable fluid 4 Transfusion stimulates the impaired defense mechanism The author employed transfusion in sixteen cases of severe puerperal infection The brief clinical histories of these patients indicate that the efficacy of the blood transfusion did not come up to expectations for only five of them recovered, and in two of these the cure cannot be ascribed to blood transfusion However, transfusion had good symptomatic effects in many cases, the pulse improved, the temperature decreased, the continuous chills were interrupted and the patients felt relieved. Although the curative effect of transfusion was not as valuable as expected in puerperal sepsis, transfusion did prove its efficacy in chronic secondary anemia of patients with myoma or metropathia and also in acute secondary anemia following severe loss of blood after delivery or after abortion

Diphtherial Vulvovaginitis—Unsel reports the clinical history of a girl, aged 8, who developed a severe vulvovaginitis, together with slight pharyngeal symptoms Bacteriologic examination corroborated the assumption that the condition was caused by diphtheria bacilli, and treatment with large doses of diphtheria serum was resorted to and proved effective The complications, such as myocardial and renal impairments, visual disturbances, and paralysis of the uvula and of certain muscles of the neck and the back, all disappeared again The source of the infection could not be definitely established, but the author assumes that the child became infected in a children's home in a spa, for the condition developed a few days after return from the spa. He considers the vulvovaginitis secondary and the pharyngeal conditions primary, although the pharyngeal symptoms were much less severe.

Value of Ruge-Philipp Virulence Test—A review of the literature on the subject, according to Waitz, points to a preponderance of favorable opinion as to the practical value of the Ruge-Philipp virulence test. The latter consists in determining the relation of the invasive power of the vaginal micro-organisms to the bactericidal quality of the blood of the person. The author applied the test in the gynecologic clinic of Zwickau in 195 operative and 63 obstetric cases. He found that the presence of virulent organisms in the vaginal flora suggests later complications but does not establish a definite prognosis. The presence of nonvirulent organisms insures a smooth convalescence almost without an exception. The test gives a valuable indication in the preparation of a patient for a gynecologic operation. A virulent flora can be attenuated or changed to a nonvirulent one through the use of antiseptic vaginal douches. The presence of virulent organisms in a case of abortion is an indication for conservative treatment. The test gives valuable indications in the irradiation of uterine cancer. To avoid an infection it is advisable, in the presence of virulent germs, to spend some time in an attempt at disinfecting the genital tract before applying the radium. The same holds true for roentgen therapy. In the course of a severe infection of the genital tract the test offers an index to the power of resistance of the organism. The application of the test implies the cooperation of a well equipped bacteriologic laboratory. The author concludes that the virulence test offers, when used in conjunction with clinical observations, a valuable aid to prognosis, prophylaxis and treatment of gynecologic and obstetric conditions.

Schizosaccharomyces Hominis in Blood of Umbilical Cord—Benedek was able to obtain a pure culture of this vegetative parasite from the contents of a cantharides blister

in 90.5 per cent of the cases. The streak method was used in making the cultures. The microscopic preparations were stained with the May-Grünwald-Giemsa stain. The author believes that *Schizosaccharomyces* is a permanent endoparasite of the human species. Transmission of the infection from one human subject to another is accomplished in the uterus. The author was able to demonstrate the passage of parasites from the maternal to the fetal circulation by examination of the blood from the umbilical cord. The blood thus obtained was centrifuged and submitted to the cultural method of study. The author was able to cultivate the parasites in 31.66 per cent of 657 specimens of blood from the umbilical cord.

Danger of Infection in Operative Opening of Stomach—Madlener states his belief that, in the prevention of infection within the peritoneal cavity, it is more important to preserve the vitality of the peritoneum than to keep out the infection at all costs. For the last ten years he has abandoned the use of occluding clamps except in cases of gastric carcinoma, a pre-operative lavage of the stomach and the use of the sucker during the operation were relied on to limit the soiling of the peritoneum with gastric or intestinal contents. During that time he has performed 206 partial gastric resections and forty-one gastro-enterostomies. There were no fatalities in the gastro-enterostomy group, there were six fatalities in the gastric resection group, slightly less than 3 per cent. Of these, only two were the result of infection. The observations from the clinics of Anschütz and of Stich demonstrated that the gastric and duodenal contents in the cases of peptic ulcer are usually sterile or contain nonpathogenic organisms. In cases of gastric carcinoma, the flora is rich in pathogenic organisms. In the last five years the author has operated in forty cases of gastric carcinoma without the use of occluding clamps. In this group there were three deaths caused by the operation, two being due to peritonitis. Drainage was omitted in all save four cases giving special indications. The stomach was washed out before the operation with water acidulated with hydrochloric acid. In the postoperative histories of the surviving 237 cases of partial gastric resection there was not an instance of a severe infection, of an intraperitoneal abscess or of a diffuse suppuration of the abdominal wall. The author ascribes the relative freedom from infection to the omission of the occluding clamps. This permits of minimizing the amount of trauma to the peritoneum, of performing a more accurate anastomosis, and of a more direct and accurate hemostasis.

Endometriosis—Endometriosis according to Seitz, presents three main characteristics: (1) It is essentially a normal endometrium in an atypical location; (2) it exhibits a tendency to proliferation and invasion of the neighboring tissue; and (3) it responds to hormonal ovarian influence with a menstrual

reaction in the same manner as the normal endometrium. The clinical picture varies with the localization. In the sixty-five cases observed by the author, the growth was localized as follows: uterus, nineteen times, tube, eight times, ovary, twenty-three times, pouch of Douglas, four times, urinary bladder, three times, parietal and visceral peritoneum, four times. Three fairly typical clinical pictures, depending on the localization, can be differentiated: (1) endometriosis within the uterine musculature, (2) retrocervical and (3) intraperitoneal, with localization in the ovary, the tube or the uterosacral ligaments. The most noticeable symptom in the first variety is increased and prolonged menstrual flow. Dysmenorrhea is common. The uterus is uniformly enlarged and hard. Curettage does not stop the bleeding permanently, nor do the roentgen rays. Retrocervical growths can be recognized on rectovaginal palpation. It is this type that displays the greatest tendency to proliferation and invasion. The growth commonly involves the uterosacral ligaments, the posterior wall of the vagina, the vagina, the rectal wall and the rectum. Robert Meyer demonstrated the histolytic properties of these cells resembling sarcoma and suggesting that the growth is a true blastoma. While the tumor itself is not malignant, it brings about a tendency to malignant transformation in the adnexa. Intraperitoneal endometriosis begins, as a rule, in the ovary and invades the adnexa, forming a conglomerate tumor. The premenstrual histologic changes are most pronounced in this localization, probably because the growth is not compressed, as is the case with the intra-uterine tumor. This menstrual reaction leads to bleeding with formation of chocolate cysts in the ovary or the tube and to bleeding into peritoneal tissues. The resulting peritoneal irritation gives rise to severe premenstrual and menstrual pains, frequently associated with rectal and vesical tenesmus. The treatment presents many difficult problems. In women about the menopause, the author recommends roentgen irradiation, high dosage being employed, as for carcinoma. Surgical intervention is preferable in young women. The author attempted in such cases to conserve at least one ovary and the uterus. This procedure yielded 13 per cent of recurrences requiring a complete extirpation at a secondary operation.

Hepatopathy of Pregnancy and Pathogenesis of Eclampsia—Hofbauer states that the liver in the second half of pregnancy shows special histologic changes. These are: (1) stasis of the central veins, (2) disappearance of glycogen and its replacement with fat droplets, and (3) biliary stasis. As a functional corollary of these changes, he points to alimentary levulosuria, urobilinuria, tendency to acetonuria and to elimination in urine of amino-acids and polypeptides after their oral administration, and to increase in the ketone bodies of the blood. A modified von Bergmann bilirubin elimination test, applied in fifteen women in the first half of pregnancy, showed retention within normal limits. The test in women in the second half of pregnancy showed a moderate retention in seventeen out of twenty. The author concludes that the conception of "liver of pregnancy" in the sense of von Bergmann is further supported by the experiments just quoted. In a previous work the author demonstrated the passage of syncytial cells of the fetus into the maternal circulation. These elements are responsible for the stimulation of the epithelial elements of the pituitary, the thyroid and the suprarenal gland to hyperplasia and hypertrophy. The syncytial albumin introduced into the maternal blood is capable of inducing liver damage and diminution of glycogen. It was demonstrated in a previous work that the histamine-like action of the fetal albumin on the liver and the kidney can be retarded by injections of insulin. The syncytial processes contain a ferment that may be responsible for liver damage. The author believes that this liver damage is the starting point in the development of eclampsia, which results from hyperfunctioning of the pituitary and the suprarenal hormones in the circulating blood. One of the functions of the liver is to retain these hormones or combine them. The failure to destroy the pressor hormone of the posterior part of the pituitary results in irritation of the higher centers of the brain with permanent increase in the blood pressure. The subsequent deprivation of oxygen, edema and increase in pressure of the brain result in eclamptic convulsions. The hormone produces an antidiuretic and vasoconstricting effect on the kidney. The treatment should be directed to suppression of the hormone of the posterior half of the pituitary gland and to protection of

the liver function. In the active treatment, intravenous injection of dextrose is most rational because it protects the liver parenchyma, combats acidosis, supports the heart and provokes diuresis. Eclamptic patients are poor surgical risks. The interruption of pregnancy, however, is an ideal procedure because the removal of the placenta removes at once the stimulus to pituitary hyperfunction.

Hygiea, Stockholm

94 929 960 (Dec 15) 1932

*Apoplectic Hemorrhage of Brain and Softening of Brain F. Tisell—p 934

Apoplectic Hemorrhage of Brain—Tisell says that the most common cause of hemiplegia is cerebral hemorrhage, then encephalomalacia due to thrombosis, general arteriosclerosis or embolism, more rarely brain tumors, pachymeningitis or subdural hematoma. The age is helpful in diagnosis only before 60 and after 80. Cerebral hemorrhage is the most common cause of hemiplegia before 60, hemorrhage and softening of the brain are about equally frequent as the cause between 60 and 70 and even between 70 and 80, and encephalomalacia is the usual cause after 80. The course in cases of encephalomalacia is more protracted. A patient with cerebral hemorrhage who survives the fifth day usually recovers. Before the end of the first twenty-four hours, nothing can be said as to the prognosis. On the whole, a low or normal blood pressure (under 150) immediately after the attack points to softening of the brain, a high blood pressure (over 250) is rather an indication of hemorrhage. Tabulation of 121 cases is given.

*Blood Sugar Curves After Dextrose Orally and in a Few Cases Intravenously in Certain Acute Infectious Diseases A. Brems and N. J. Nissen—p 1203

Typewriter as Aid in Differential Count of Leukocytes A. Bøge—p 1206

Blood Sugar Curves After Dextrose in Infectious Diseases—Brems and Nissen state that, in pneumonia and angina, sometimes in uncomplicated influenza and measles, and in erysipelas, the alimentary blood sugar curve of the patients is frequently abnormal after ingestion of about 1 Gm of dextrose per kilogram of weight. They consider this abnormal alimentary hyperglycemia a sign of a universal intoxication of the organism, which may possibly pave the way for diabetes, particularly in predisposed patients. The frequent absence of glycosuria in spite of blood sugar values over 200 and up to 260 mg per hundred cubic centimeters probably depends on a toxic injury of the kidneys. Normal alimentary blood sugar curves are often seen in highly febrile patients. Abnormal blood sugar curves after dextrose intravenously in two patients with influenza and angina respectively are shown as further proof that the abnormal alimentary hyperglycemia in patients with acute infectious diseases cannot result from changed conditions of resorption but must be due to a disturbance of the blood sugar regulation caused by intoxication.

Laryngospasm in Child Aged 6 Tracheotomy H. Videbech—p 1235

Colored Eye Ointment H. Ehlers—p 1236

Open Tuberculosis in Children—Hasle's material comprises 496 certain cases of open tuberculosis in children given sanatorium treatment from 1911 to 1926. Two thirds of all patients are girls, one third, boys. The fate of fifty-six is unknown. Five years after discharge, about 64 per cent of the 440 were dead, about 28 per cent were well and able to work, about 2 per cent were partly capable of work, and about 6 per cent were ill. About one third of the number died within one year after the establishment of bacilli, with an average length of life of seven months after establishment of bacilli, and fully one half died within three years, with an average length of life of thirteen months. Half of the girls died within two years after establishment of bacilli and about one half of the boys during the first four years, with an average length of life after establishment of bacilli of about ten and sixteen months, respectively.

THE PATHOGENICITY OF THE FUSIFORM BACILLUS AND SPIRILLUM OF PLAUT-VINCENT

A CLINICAL AND EXPERIMENTAL STUDY

HENRY H. LICHTENBERG, M.D.
NEW YORK

MARIE WERNER, B.S.
AND

ESTHER VOLCKMANN LUECK, B.A.
CHICAGO

It has been quite generally accepted that the Plaut-Vincent organisms have a pathogenic relationship to a variety of clinical entities. Unexceptionable proof of such relationship is wanting. The purpose of this report is to record clinical and experimental observations bearing on this subject. This study was undertaken at the suggestion of Dr. Joseph Brennemann.

In the course of a study of a large series of diphtheria patients Plaut,¹ in 1894, came on five cases of non-diphtheritic membranous angina, at first taken for diphtheria, in which fusiform bacilli and spirochetes were found. Plaut called these "Miller's organisms," since these had been described in 1883 by an American dentist, Willoughby D. Miller, who stated that pathogenic properties had already been ascribed to these organisms by Verneuil and Clado, who had found them in abscesses of the sublingual salivary gland, in submaxillary adenitis and in an abscess of a finger due to a human bite. Although the organisms were found beneath the gum margins in almost every mouth, and their numbers were greatly increased in gingivitis, Plaut believed them to be the causative agent in the anginas because the organisms were present in such great numbers, in two instances in pure culture.

In 1896, and more fully in 1899,² Vincent² described two diseases of the mucous membrane of the mouth and pharynx which he ascribed to the fusospirochetal organisms. The first was a mild stomatitis with superficial ulcerations, with a subfebrile course lasting two or three days. The ulcerations were covered with membranes, which came off easily but reformed to a less degree and gradually disappeared. In the second form a deep ulcer, which bled easily, lay beneath the membrane; the fever was high and a marked adenitis and a reddened edematous pharynx were present. The disease ran a protracted course, in one patient for two months. In the first form he found only the fusiform bacillus while in the severer, ulceromembranous form

the bacillus was associated with a spirillum in fifteen out of eighteen cases. Vincent was unable to reproduce the disease in the mouth or vagina of animals, and subcutaneous injections of the mixed organisms resulted in abscesses in which only pus organisms were found. He was unable to cultivate the organisms and satisfactorily attest their pathogenicity.

Weaver and Tunnichiff³ in 1905 described the presence of the fusiform bacillus and spirillum in ulcerative stomatitis and succeeded in cultivating the bacillus anaerobically. These investigators were unable to produce any disease in rabbits with pure cultures. When mixed cultures were injected into the ears of rabbits, gangrene of the skin and death resulted. Smears after death, however, failed to show fusiform bacilli or spirochetes. Only diplococci and streptococci were present. Abscesses were produced by subcutaneous injection of mixed cultures and the organisms were demonstrated on smear and recultured. The results were identical when the fusiform bacillus alone was present in the culture and when it was combined with the spirillum. Tunnichiff⁴ reported later finding spirilla in old cultures of the fusiform bacillus and believed them to be a later stage of the same organism. Other investigators⁵ do not agree with this interpretation.

Of the many other attempts to prove the pathogenicity of these organisms, the investigations of Kline⁶ and of Smith⁷ are especially noteworthy. The former traumatized the muscles of his animals with a hemostat and injected into the injured part material from gangrenous lungs containing a mixture of fusospirochetal and other organisms. Gangrene with foul smelling pus developed and the animals died. In untraumatized muscles only a small area of infiltration was present in 78 per cent of his animals. Two of three rabbits injected intrabronchially through a tracheotomy tube with the mixture of organisms developed pulmonary gangrene. The results with material from Vincent's angina, dental caries and pyorrhea were identical.

At first Smith^{7b} was also unable to produce abscesses in the groins of guinea-pigs with material from Vincent's angina without lowering the resistance of the tissue by trauma. When, however, two animals were brought to the bedside of the patient and the material was injected with a minimal exposure to the air, typical fusospirochetal abscesses developed in two weeks and were transmitted from animal to animal for fifteen

passages. In 20 per cent of some 100 animals Smith produced lung abscesses by intratracheal injection, under ether anesthesia, of the bloody scrapings from moderately severe pyorrhea, simulating the conditions in man during major operations under ether anesthesia. He concluded that the common cause of lung abscess is a mixture of anaerobic organisms, the fusiform bacillus, spirochetes, a vibrio and a hemolytic streptococcus. In all but one of fifty-six cases of lung abscess (spontaneous, bronchiectatic, postoperative, postpneumonic, neoplastic and tuberculous), collected from the literature in which bacteriologic and pathologic studies were made two or more of these organisms were reported present.

Smith made separate cultures of these organisms and injected guinea-pigs with pure cultures, singly and combined. Only a mixture of *Treponema microdentium*, a small fusiform bacillus, a vibrio, and a hemolytic streptococcus would produce the typical foul smelling abscess. With pus from these lesions similar lesions were produced in the lungs of rabbits.

We attempted to lower the resistance of the tissues in guinea-pigs sufficiently to allow the fusiform bacillus in pure culture to gain a foothold. The organism was isolated from spongy gums, and a four-day-old broth subculture was used. Under ether anesthesia the muscles of the hind legs were exposed and severely crushed with a hemostat, and 1 cc. of the broth culture was injected. In a second group boiling water was injected into the muscle, followed several minutes later with 1 cc. of the culture. Other animals were injected with mixtures of the fusiform bacilli, streptococci and staphylococci. These experiments and others with minor modifications were always negative.

If it is assumed for the moment that the Plaut-Vincent organisms, which are probably present in every mouth after the teeth are erupted and in sufficient numbers to be easily demonstrated in from 30 to 80 per cent of individuals, are saprophytes, one might expect to find their numbers very much increased when dead tissue as a result of a clean surgical wound of the buccal mucous membrane is present for them to grow on. The membrane covering the tonsillar beds following tonsillectomy furnishes good and abundant material for investigation. Children up to the age of 13 years, admitted to the Children's Memorial Hospital for tonsillectomy, were studied. For several weeks previously and at the time of operation they were well and had no fever, infection of the upper respiratory tract, or injected pharynx. Immediately following the operation, smears were made from the surface and crypts of the extirpated tonsils and were examined for Vincent's organisms and leukocytes. The children were seen again on the fourth or fifth postoperative day. The condition of the throat, gums and teeth was recorded, and smears were made from the green-gray mucoid, at times dry and cheesy, membrane covering the tonsillar fossae.

Of 125 patients, 108 returned for follow-up study and are included in the series. In fifty (46 per cent), fusospirochetal organisms were present in smears of the tonsils themselves. In thirty-nine (78 per cent) of the fifty, the fusiform bacillus alone was found, while in eleven (20 per cent), both fusiform bacilli and spirilla were present. Only a few organisms were seen in the smears of thirty-seven (68 per cent) cases. In six (12 per cent) they were present in sufficient numbers so that the smears could easily be taken for those coming from cases of Vincent's angina.

On the other hand, fusospirochetal organisms were found in ninety-eight (91 per cent) of the smears from the membranes covering the tonsillar beds. In forty-nine (50 per cent) of these ninety-eight only fusiform bacilli were seen, in the remaining 50 per cent both organisms were present. In thirty-one (31.5 per cent) only a few organisms were found, while in seventeen (17.3 per cent) instances they were so numerous that a diagnosis of Vincent's angina might seem justified from the smears.

While no fusospirochetal organisms were found in smears from the tonsils themselves in 58 (54 per cent) of the 108 cases, they were present in 98 (91 per cent) of the smears from the membranes following operation.

In seventeen cases (16 per cent) the organisms were somewhat more numerous in the smears from the tonsils than in those from the membrane covering the fossae. The difference was usually only slight. In seven of these cases a few organisms were present in the tonsillar smears, while more were found in the smears from the membranes.

These figures probably minimize the actual difference in incidence and number of organisms on the tonsils and on the postoperative membranes covering the tonsillar fossae. Careful, excellent smears could be made from the extirpated tonsils. The children, however, were often refractory and feared being hurt with the applicator. We were frequently able only barely to touch the surface of the membrane with the cotton applicator before the child drew back and resisted any further attempt. The possibility of causing bleeding made it undesirable to resort to any strenuous methods, and we had to be content with this meager material.

In forty out of eighty-six cases in which the condition of the teeth and gums were noted, an abnormal condition varying from small deposits of tartar to many carious teeth and swollen gums with exudate along the margins was found. Of these, eighteen (45 per cent) had only a few fusospirochetal organisms in smears from the postoperative membranes. In twenty-seven (59 per cent) of the remaining cases with apparently normal gums and teeth, the smears showed many of these organisms. Of the seventeen patients with very many organisms in the smears of the membranes, nine had normal teeth and gums and eight had some abnormal condition. Similarly, we noted no constant relationship between the intensity of the injection surrounding the tonsillar fossae or the number of pus cells seen in the smears and the number of Vincent's organisms.

All but one of the 108 children were seen two or more times postoperatively. For the most part, the cases ran the usual, uneventful course to recovery. Six children had a severer course, two developed acute bronchitis, one acute purulent otitis media, one unexplained fever at night for ten days, and two had more than the usual amount of pain on swallowing for a week. Of the six, two showed many and four only a few fusospirochetal organisms in the smears from the membranes.

Guinea-pigs were subjected to analogous conditions. Smears were made from the normal gums of three guinea-pigs. Neither fusiform bacilli nor spirilla were seen in these. Under ether anesthesia the mucous membrane below the lower teeth was abraded with a sterile scalpel till an ulcer was produced and bleeding occurred. Three days later a dry, cheesy exudate, a loosely attached dirty gray membrane, covered the ulcerated

areas. In smears from these in every instance were shown many fusiform bacilli and spirilla indistinguishable from those obtained from human subjects. The fusiform bacillus showed also the same cultural characteristics as those we recovered from spongy gums of human mouths. Five days later the lesions were clean and almost healed, but the organisms were still abundant. On the twelfth day the lesions were healed, but the organisms were present for two days longer. The experiment was repeated with six more animals with identical results.

The methods and drugs used in the treatment of lesions attributed to these organisms are legion. Local applications⁸ of tincture of iodine, chromic acid, glycerin, formaldehyde, potassium chlorate, sodium perborate, acriflavine hydrochloride, copper sulphate, methylene blue (methylthionine chloride, U S P), gentian violet, mercurochrome and hexylresorcinol have all been used, supposedly with good results. Jelinek⁹ reported rapid cures in ulcerative stomatitis and Plaut-Vincent's angina in a large group of soldiers by freezing the lesions with ethyl chloride, and he advises its use in other fusospirochetal conditions such as pyorrhea. Gerstenberger¹⁰ reported that he cured his cases of ulcerative stomatitis with water-soluble vitamin B and believed that an insufficiency of this vitamin in the diet played an important role in the etiology of stomatitis. Driscoll¹¹ had good results with the injection of 5 cc of a 10 per cent solution of antimony and potassium tartrate and believed it specific for Vincent's angina.

In the last decade, probably as a result of success against the spirochete of syphilis, the arsenic derivatives have become popular in the treatment of conditions in which the fusospirochetal organisms are found. In 1923, Morgan¹² used injections of neoarsphenamine in ulcerative stomatitis in which he found these organisms, with improvement in two and a half days, and cure in five and a half days. Eight patients treated both intravenously and locally were well in five and three-quarters days. Barenberg and Bloomberg⁸ used intramuscular injections of sulpharsphenamine alone and combined with local application. The former group cleared up in seven days, the latter in five. The authors state that the treatment did not, however, rid the mouth of the fusospirochetal organisms. Rosenbaum¹³ reported good results from the use of acetarsone by mouth in ulcerative stomatitis. He treated his cases first with acetylsalicylic acid for from twenty-four to forty-eight hours and since they were not improved, gave acetarsone with improvement often in twenty-four hours. Similarly, good results have been claimed for the arsenicals in gangrene and abscesses of the lungs in which these organisms are present.¹⁴ A review of the

combined case reports shows cases in which the pulmonary abscess healed rapidly and spontaneously, and others that improved only for a time with arsphenamine treatment and finally had a fatal outcome.

In view of the evidence for the efficacy of the arsenicals in the treatment of lesions attributed to these organisms, it becomes difficult to explain the presence of these micro-organisms about the gums and in syphilitic ulcerations of the mouth of patients undergoing active antisyphilitic treatment. It is even more awkward to explain the development of an acute Vincent's angina in these patients.¹⁵ Sutton¹⁵ in this connection justly raises the question that if sulpharsphenamine is of value in the treatment of Vincent's angina, should not a comparatively high body saturation protect the individual against the disease?

Four of a group of eight guinea-pigs were injected intraperitoneally with 25 mg of sulpharsphenamine per kilogram of body weight on alternate days for four doses. Smears made from the mouths of the eight animals were negative for the fusospirochetal organisms. Under ether anesthesia, ulcerations of the gums were produced in all eight animals, as in the previous experiments. Smears were made on alternate days and the injections of sulpharsphenamine continued in the four pigs. Similar lesions were produced in a second group of six animals. The lesions in three were painted with a 10 per cent solution of sulpharsphenamine, in the control animals, physiologic solution of sodium chloride was used. In all animals a membrane formed over the ulcerations, and fusospirochetal organisms were found in all of them. The lesions in the animals treated with sulpharsphenamine healed at the same rate, and organisms remained as long as in the control animals.

Since one learns from the literature that the lesions of ulcerative stomatitis attributed to these organisms heal in some five to seven days with any one of many treatments, it seemed of interest to follow the natural course of this disease. Patients with ulcerative stomatitis who came to the outpatient department of the Children's Memorial Hospital were referred to us from the general clinic. The mild and doubtful cases were referred back and only the sixteen more severe ones with many ulcerations in the mouth and reddened, swollen gums were followed. The patients were as a rule seen first by a physician of the attending staff, the diagnosis of ulcerative stomatitis was made, and they were then referred to us. The patients varied in age from 13 months to 12 years. They all had concurrent throat infections. Smears made from the lesions usually showed a great many fusiform bacilli and spirochetes, occasionally only bacilli, and in only two children, both under 2 years of age, no organisms were found. Both of these children fought desperately, and forcing the mouth open caused such bleeding that satisfactory smears were not obtained. The course of the disease was so nearly alike in all cases that, after seeing six or seven of them, we could with a fair amount of assurance advise the parents that the child would feel better in two or three days and be entirely well in a week. We gave small doses of acetylsalicylic acid, which may have made the children feel somewhat more comfortable but can hardly be assumed to have had any direct action on the local condition. The lesions

in one case were painted with mercurochrome solution before the patient was referred to us. Another had received a dilute peroxide gargle because the odor was especially foul. The children were all well in from four to seven days. The report of a few cases is included to demonstrate the natural course of the condition.

REPORT OF CASES

CASE 1—G G, a boy, aged 7 years, seen, July 20, 1931, complained of fever, headache, sore mouth and loss of appetite of two days' duration. The pharynx was reddened and there were many small ulcerations on the tongue, lips, and buccal mucous membrane. A diagnosis of ulcerative stomatitis was made. Smears from the lesions showed many fusiform bacilli and fewer spirochetes. The laboratory diagnosis was Vincent's disease. The child was given 5 grains (0.3 Gm) of acetylsalicylic acid three times daily. Three days later the condition was somewhat worse, with new lesions on the gums and tongue. July 27, the patient came into the examining room smiling and reported that he had been feeling well and had been able to eat for a number of days. The lesions were practically healed, the membrane covering the ulcerations entirely gone. He was not seen again for a month, when it was reported that he had remained well.

CASE 2—M R, a girl, aged 4 years, seen, Aug 13, 1931, complaining of a sore mouth and inability to eat for three days, had several ulcerations of the lips and buccal mucous membrane. The pharynx was reddened. In smears from the lesions were seen many fusiform bacilli and spirochetes, and a laboratory diagnosis of "Vincent's disease" was made. The child was given 5 grains (0.3 Gm) of acetylsalicylic acid three times daily. August 17, she was feeling well and eating regularly. The lesions were practically healed. The bases of the ulcers were small and clean. The patient failed to return for further follow up.

CASE 3—P S, a girl, aged 8 years, seen, Aug 17, 1931, complained of a cold and a sore throat of six days' duration, and sores in the mouth and on the lips for four days. There were many small ulcerations on the lips, gums, tongue and pharynx and a larger one on the palate. The pharynx was reddened. The laboratory report of examination of smears from the lesions read "Numerous fusiform bacilli and spirochetes, too many per field to count." The patient received 5 grains (0.3 Gm) of acetylsalicylic acid three times a day. Four days later, August 21, she was feeling well. The gums and mouth appeared normal except for a small, clean, healing ulcer on the palate. The patient failed to return for further follow up.

CASE 4—V B, a boy, aged 12 years, seen by an attending pediatrician in the outpatient department, Aug 24, 1931, complained of a sore throat and pain on swallowing of four days' duration. There were many ulcerations on the palate, buccal mucosa, gums and posterior pharyngeal wall. In smears from the lesions were many fusiform bacilli and spirochetes. A laboratory diagnosis of Vincent's angina was made and the lesions were painted with mercurochrome.

We saw the patient for the first time, August 26. He was feeling somewhat better but still had considerable pain on swallowing. There were many small ulcerations covered with a dirty gray membrane on the tongue, lips and palate. The gums were reddened and swollen, and exudate was present along the gingival margins. The patient was given 5 grains (0.3 Gm) of acetylsalicylic acid three times daily. August 28, he was feeling perfectly well. The mouth was healed except for two small, clean ulcerations.

CASE 5—S P, a girl, aged 2 years, was brought to us, Aug 26, 1931, with the history of having had a cold and fever for nine days and swollen gums covered with white spots for four days. The child was irritable and refused to take anything but water and a little milk. The mucosa of the pharynx and mouth was reddened, the gums were swollen and bled easily. Many small ulcerations were seen on the gums and buccal mucosa. Smears from these showed many fusiform bacilli and somewhat fewer spirochetes. The child was given 2 grains (0.13 Gm) of acetylsalicylic acid three times a day.

August 31, she was feeling well and was taking solid food. The throat was still slightly reddened, but the ulcerations were healed and the gums were swollen only about one canine tooth. Four days later the mouth and pharynx appeared entirely normal. The child was eating well and had gained weight.

CASE 6—A R, a girl, aged 3 years, seen Sept. 22, 1931, had been ill with fever and a sore mouth for four days. The throat was inflamed and a mucopurulent discharge could be seen dripping down from the nasopharynx. There were many small ulcerations on the gums, tongue and buccal mucous membrane. Smears from the lesions showed the presence of fusiform bacilli but no spirochetes. The child was given 2 grains (0.13 Gm) of acetylsalicylic acid three times a day.

Three days later the lesions were clean and healing. The child ate well and had gained weight. September 28, only faint outlines of the former ulcers were still visible. The mouth was otherwise normal and the child well.

CASE 7—R T, a girl, was seen, April 22, 1931, because of an infection of the upper respiratory tract. The mouth at this time was normal. Two days later the general condition of the patient was worse and there were many shallow ulcerations covered with dirty gray membrane on the buccal mucosa and on the anterior tonsillar pillars. In smears from the lesions, fusiform bacilli but no spirochetes were seen. The patient was given 5 grains (0.3 Gm) of acetylsalicylic acid three times a day.

She was seen by one of the attending pediatricians, April 28. He reported that the lesions were entirely healed and that the child was well.

COMMENT

Failure to produce lesions in animal experiments with pure cultures of the fusiform bacillus alone, or by injection into traumatized tissue, obviously has no conclusive significance. The organisms may have lost their virulence during the process of isolation or the laboratory animals may not have been susceptible. When, however, these organisms are found in practically every normal mouth, about spongy gums, in pyorrhea alveolaris, ulcerative stomatitis, angina, tonsillitis, diphtheria, scarlet fever, stomatitis due to mercury and bismuth compounds, syphilitic ulcerations of the mouth,¹⁶ noma, ulcers of the bronchial mucosa, and bronchiectasis, in tuberculous, neoplastic, spontaneous, postpneumonic and postoperative lung abscesses, around the clitoris or the uncircumcised penis, in vulvitis, vaginitis, and balanitis gangraenosa,¹⁷ it seems improbable that these organisms play the determining rôle in the causation of all these conditions. It would seem at least as probable that they are saprophytes and opportunists growing on lesions caused by other agents and only rarely, if ever, becoming pathogenic.¹⁸ Our finding that in clean surgical wounds of the mucous membrane of the mouth and pharynx, in guinea-pigs and children alike, the number of fusospirochetal organisms increases markedly, seems further support of this view.

One may well question also the rationale of taking smears for Vincent's organisms in ulcerative stomatitis and anginas for diagnostic purposes. Whether many, few or no fusospirochetal organisms, singly or combined, are found, the interpretation of the case and its course remain unchanged. In the present status of knowledge, we feel justified in questioning a fusospiro-

chetal pathogenicity, and that is our sole purpose in this report. In the last analysis, the onus probandi would seem to rest with those who maintain that these organisms are pathogenic.

SUMMARY

1 Attempts at producing lesions in any way similar to those commonly attributed to the action of the Plaut-Vincent organisms by injecting pure cultures of fusiform bacilli into areas of traumatized tissue in guinea-pigs were unsuccessful

2 The fusospirochetal organisms were found in 45.4 per cent of tonsils removed from 108 children

3 In the same children these organisms were found in 91 per cent of the membranes that formed over the tonsillar beds after tonsillectomy, and usually in greater numbers than in the tonsils themselves

4 The organisms were found constantly in smears of the membranes that formed over traumatic ulcers produced in the mouths of guinea-pigs

5 Neither the injection nor the local application of sulpharsphenamine hindered the appearance of these organisms in the lesions in the mouth of guinea-pigs or hastened the healing of the lesions

6 Sixteen consecutive cases of severe ulcerative stomatitis in children all healed in some four to seven days without treatment. This compares favorably with the reports of cases treated with various drugs and other forms of treatment

7 The value of diagnostic smears for Vincent's organisms as a means of establishing a pathogenic relationship of these organisms to a suspected lesion is questioned

HEART IN BILATERAL OBSTRUCTIVE
EMPHYSEMA DUE TO TRACHEAL
FOREIGN BODIES

SHERWOOD MOORE, MD

HUGH M WILSON, MD

AND

M F ARBUCKLE, MD

ST LOUIS

Obstructive emphysema due to foreign bodies in the bronchi was described by Iglaue¹ in 1912. Since then, numerous articles on the localization of nonopaque foreign bodies through the presence of obstructive emphysema have appeared in the literature. Notable are those of Manges² and Jackson³. The recent work of Lundskog and Van Allen⁴ on the experimental production of obstructive emphysema has greatly increased the knowledge of the physiology of the subject. They

have shown that obstructive emphysema occurs whenever a main bronchus is obstructed by a one-way valve mechanism which permits the ingress of air during inspiration and retards its egress from the lobe during expiration. They found also that obstruction of a complete lobe is necessary for the production of obstructive emphysema. Because of collateral respiration, lobular expiratory obstruction is not followed by obstructive emphysema unless there is interference with

Fig 1—Animal roentgenographic table. The inset shows tracheal tube with olive and flutter valve attached

the collateral respiration of the part from inflammatory changes in the lung. The radiologic signs of unilateral obstructive emphysema have been listed by Manges as: (1) increased transparency of the affected lung, (2) depression and partial fixation of the diaphragm on the affected side, (3) the displacement of the heart and mediastinal structures away from the affected side, (4) increased excursion of the diaphragm on the unaffected side."

An example of bilateral obstructive emphysema resulting from tracheal foreign body is illustrated in his article by films taken in full expiration both before and after removal of the foreign body. Manges states that the "diaphragm [is] depressed on both sides and is lower on expiration than on inspiration, being overcome by the more powerful intercostal muscles of respiration, the heart is more vertical appearing in its entirety above the diaphragms."

At the risk of being irrelevant we would remark at this point on the difficulties of securing films of the chest at full inspiration and full expiration in infants, young children or adults who are unconscious or delirious. We have succeeded in overcoming these by the method described later, which is also applicable to experimental animals.

In studying a recent case of suspected foreign body in the trachea, one of us (Wilson) was impressed by the difference in size of the cardiac silhouette in the inspiratory and expiratory films of the chest. In the fluoroscopic examination of this patient preceding bronchoscopy it was noted that both leaves of the diaphragm occupied low positions and had little respiratory excursion. At the moment of full expiration the heart seemed "squeezed" between the two overinflated lungs and showed a marked diminution in its size. This decrease is far in excess of that existing between the extremes of cardiac systole and diastole. With the onset of the next inspiration and release of pressure, the heart assumed its normal size and shape.

Bronchoscopy was performed by Dr Aibuckle. A foreign body (peanut) was found obstructing the trachea a few centimeters above the carina. Widening of the air passage with each inspiration and narrowing during expiration producing an expiratory valvular obstruction was observed bronchoscopically. The foreign body was removed. Films taken the following day in full inspiration and expiration revealed normal cardiac size and relationships in both respiratory phases. It will be seen in the films taken before removal of the foreign body that both leaves of the diaphragm occupy a slightly lower position on expiration than on inspiration,² both lung fields show greater air content than normal, and the cardiac transverse diameter shows a decrease of 1.3 cm on expiration. The cardiac apex lies opposite the lower border of the eleventh vertebra in both films, indicating an actual decrease in cardiac size rather than lengthening as a result of the depression

figure 1, was attached to one limb of the Y, the second arm being connected to the mercury manometer in order to obtain intratracheal pressure readings. Control films of the chest were made in inspiration and expiration, inhalations of 10 per cent carbon dioxide-oxygen mixture being used to secure full inspiratory and expiratory excursions of the chest wall and diaphragm. The olive of proper size with the attached tube was introduced into the upper trachea by a laryngoscope. The mercury manometer and flutter valve were then attached to the Y arms and the development of obstructive emphysema was observed fluoroscopically. Films were taken in inspiratory and expiratory phases of respiration with the animal in the supine position on the animal radiographic table (fig 1). This table is fitted with a canvas sling to suspend the animal above a trochoscope, which permits fluoroscopic observations and the making of roentgeno-

of the diaphragm by the overinflated lungs, as claimed by Manges. During the past few months we have seen three other cases of foreign bodies which have shown bilateral obstructive emphysema with the "cardiac squeeze" easily demonstrable on fluoroscopic examination and a marked decrease in cardiac size in the film taken in expiration. In order to confirm the changes in heart shadow observed in these cases and to determine whether or not the compression of the heart and great vessels by the overinflated lungs contributes to the signs of bilateral obstructive emphysema, we undertook some experimental studies of artificially produced bilateral obstructive emphysema.

METHOD

We employed a long hollow brass tube with threaded ends, to one of which could be fitted metal olives of varying size to serve as obturators of the trachea. The other end of the tube was fitted with a Y connection piece. An ordinary flutter valve, as indicated in

grams by simply substituting the cassette for the screen and changing the exposure factors. This insures a true postero-anterior exposure (the most desirable), and it is unnecessary to move the animal. The exposure time used was one-twentieth second. Exposures were made with the animal in postero-anterior, lateral and oblique projections. Complete expiratory valvular obstruction could be instituted at will by attaching or detaching the flutter valve. Manometric readings were noted from time to time during the experiments. Accurate tracheal pressure readings could be obtained only with the valve in place, making a closed system, though oscillations of the mercury were noted without the valve in place. These varied from minus 10 to 20 mm of mercury (inspiration) to plus 10 to 20 mm of mercury (expiration) with quiet breathing. With the institution of expiratory valvular obstruction the intratracheal pressure mounted as the amount of trapped air increased, so that marked obstructive emphysema readings of minus 2 to 5 mm of mercury on inspiration and

plus 40 to plus 60 mm of mercury on expiration were noted

The control films were compared with the films taken during tracheal obstruction and the transverse cardiac diameters measured. These measurements were made by dropping a perpendicular from the spinous process

bronchoscopy failed to reveal the presence of obstructive emphysema. Because of the suggestion of a "cardiac squeeze" noted fluoroscopically, these films were repeated in the erect position and show a decrease in cardiac shadow on expiration

COMMENT

The chest roentgenograms in four cases of obstructive emphysema show identical conditions of (1) decrease in size of cardiac silhouette, (2) overinflation of the lungs, and (3) depressed diaphragms in the expiratory phase of respiration. The percentage of decrease in the size of the heart as measured by surface area in these cases varied from 8 to 25. The decrease in transverse diameter varied from 8.8 to 28 per cent.

The experimental films of four dogs, on each of which repeated observations were made, showed well developed bilateral obstructive emphysema as a result of expiratory valvular obstruction and definite "cardiac squeeze" with each expiratory effort on fluoroscopic examination. Measurements of the transverse cardiac diameter showed a decrease of from 6.8 to 14 per cent with expiratory valvular obstruction. Planimetric measurements showed a decrease of from 7 to 10 per cent in surface area as compared with surface area on inspiration.

The explanation of the decrease in cardiac size is to be found in the famous experiments of Valsalva⁵ (1760), who first observed on man the swelling and emptying of the jugular vein coincident with expiration

Fig 2 (case 1)—A and B taken on inspiration and expiration respectively before removal of foreign body (peanut in trachea). C and D taken on inspiration and expiration respectively the day following removal of the foreign body.

of one of the upper dorsal vertebrae through the heart shadow and taking the usual median right and left cardiac measurements their sum being taken as the transverse diameter of the heart.

The surface area of the heart shadow was measured by planimetric tracings and is given as a check against the changes indicated by the measurements of the transverse diameter of the heart. Cardiac size in square centimeters surface area is given in table 1, together with the differences observed in inspiration and expiration and the percentage of decrease in surface area on expiration with tracheal valvular obstruction.

The same procedure was carried out with the films of the four cases of tracheal foreign bodies. The roentgenograms in the first three cases were taken with the patient supine at a four foot (12 meters) target film distance and exposure time of from one-thirtieth to one-twentieth second. When cooperation of the patient was impossible because of crying or struggling especially in infants we used inhalations of small amounts of 10 per cent carbon dioxide-oxygen mixture administered through a tunnel held in front of the nose and mouth. With the increased amplitude and slowing of respiration that results we can usually obtain fairly satisfactory films in full inspiration and expiration. In case 4 (table 2) follow-up films after removal of the foreign body were not obtained because of the patient's early discharge from the hospital. However, one set of films taken with the patient supine before

Fig 3 (case 2)—A and B taken on inspiration and expiration respectively before removal of foreign body (sand burr in larynx). C and D taken on inspiration and expiration respectively the day after removal of the foreign body.

and inspiration. 'If the glottis is closed after a deep inspiration and a strenuous and prolonged expiratory effort is then made such pressure can be exerted on the

⁵ Valsalva quoted from Luciani's Human Physiology (translated by Frances A. Welby). Circulation and Respiration. London: Macmillan & Co. 1929. 1911.

heart and intrathoracic vessels that the movements and flow of the blood are temporarily arrested"

Valsalva's experiment must be borne in mind in the interpretation of films taken to determine the presence of bilateral obstructive emphysema. Expiration against a closed glottis will produce the roentgenographic picture of obstructive emphysema due to tracheal or laryngeal foreign body. However, one should have little difficulty in the differential diagnosis if fluoroscopic examination reveals the "cardiac squeeze" repeated with each expiratory effort, together with the low fixed position of the diaphragm and increased air content of the lungs.

The inconstant presence of obstructive emphysema has been particularly emphasized by Manges in cases of unilateral obstructive emphysema. It is equally true of bilateral obstructive emphysema. We have observed one case fluoroscopically in which a movable foreign body of the trachea produced signs of bilateral emphysema, then emphysema of the right lung with swing of the mediastinal contents to the left, and a few moments later the signs of expiratory obstruction of the left lung with displacement of the heart to the right.

We have been unable to show experimentally a decrease in the size of the heart shadow as a result of incomplete tracheal valvular obstruction though some increase in the transparency of the lungs, and depression

The very marked decrease in the size of the cardiac shadow with complete expiratory valvular obstruction indicates an actual heart tamponade of brief duration during the respiratory cycle.

Beck and Isaac⁶ have shown in their experiments on pneumocardiac tamponade that with rise in pericardial pressure there occurs (1) a temporary fall in arterial

Fig 5 (dog 6) —Control roentgenograms A and B taken on inspiration and expiration, respectively (carbon dioxide inhalations). C and D taken on inspiration and expiration, respectively, with tracheal expiratory obstruction.

pressure, (2) a temporary fall in pulse reading, (3) a sustained rise in venous pressure with accentuation of venous pulsations, and (4) a rise in respiratory rate and an increase in amplitude. In bilateral obstructive emphysema, cardiac tamponade developed at the height of the full expiratory phase of respiration with compression of heart and great vessels by the overinflated lungs. This causes an obstruction of the venous flow into the thorax with decrease and arrest of venous return to the right auricle, the intrathoracic pressure on expiration mounts rapidly and probably exerts its effects on all the thoracic vascular structures in the order of their relative intraluminal pressures. With incomplete filling of the right auricle as a result of obstruction to venous return, together with obstruction in blood flow from the lungs to the left auricle, the intracardiac blood volume must be correspondingly decreased. This, we believe, accounts for the rather rapid decrease in the size of the heart observed fluoroscopically at the end of expiration in expiratory valvular tracheal obstruction.

SUMMARY

1 Fluoroscopic and roentgenographic change in cardiac outline (a decrease in size) on expiration in bilateral obstructive emphysema was observed in one

of the diaphragm may be noted with incomplete expiratory obstruction. Control films taken before and after introduction of the olive and tube into the trachea showed no other appreciable difference in cardiac size than could be ascribed to systole and diastole of the heart, though the diameter of the air passage was in some instances decreased by one half.

case of laryngeal and three cases of tracheal foreign bodies with bilateral obstructive emphysema.

2 Experimental bilateral obstructive emphysema was produced in dogs and measurements of the transverse cardiac diameter and cardiac surface area were taken. These confirm the observations noted fluoroscopically and roentgenographically in cases of bilateral obstructive emphysema resulting from foreign bodies in the larynx and trachea.

3 The use of carbon dioxide inhalation to obtain roentgenograms in full inspiration and expiration is suggested to insure the demonstration of the presence of obstructive emphysema in children and infants

THE INCIDENCE OF RINGWORM OF THE FEET IN A UNIVERSITY GROUP

CONTROL AND TREATMENT

ROBERT L. GILMAN, M.D.
PHILADELPHIA

An examination of the diagnoses made in the dermatologic clinic of a student health service discloses an incidence similar to figures arrived at in dispensary and private practice. The principal variation is due to the constancy of the age group seen—an average age of 19½ years. In a group of 390 new skin cases seen during the first six months of 1932 in the Student Health Service of the University of Pennsylvania, ringworm infections in general constituted by far the largest percentage. Such a diagnosis was made 145 times, or in 37 per cent. Of these cases, ringworm of the toes was seen in sixty-nine cases, or practically 50 per cent. This is of course no real index of the occurrence of ringworm of the toes, as this number represented only those cases troublesome enough to cause the affected person to seek treatment or severe enough to be referred for dermatologic advice. The incidence of ringworm, to which I shall refer later, is of much more formidable proportions.

The cases seen in consultation were associated with symptoms and in some instances provided a definite temporary disability. Next in frequency to the toe cases was involvement of the groin, which occurred in one sixth of the ringworm patients. Of less importance, in the light of their occurrence, were plantar warts, and ringworm of the fingers, of the body and of the nails. An important consideration in student cases is the frequency with which self-treated (and mistreated) or overtreated infections are seen. This will always have to be contended with as long as the inspired accounts of ringworm cure-alls appear in the daily press and are disseminated by radio.

In our management of these cases, we were bound by two considerations to work within the therapeutic limits available, which in the main is advice and prescription medication and the necessity for getting the patient under control as rapidly as possible. The latter not only is the usual aim with all patients but is most important as a method of prevention. In the manage-

ment of these cases I generally employ the term "arrested" in lieu of the appellation "cure." If the latter does take place, and I am quite sure that it does frequently, reinfection is almost certain to follow as the patient relaxes in vigilance and exposure again takes place. Consequently both individual and mass control is most desirable. Strictly speaking, prevention is not the paramount consideration with us, as Dr. Spring, associated with me in this work, has shown that entering freshmen from secondary schools are infected as high as 50 per cent.

SURVEY

We knew we were seeing but a tithe of the ringworm in the consultation room, and we desired information on the vast group of "silent cases" represented by the subthreshold clinical and symptomatic cases. In any method of control, this group is of major importance. Here were the active carriers and disseminators. Other surveys have given figures, ranging from Castellani's¹ 30 per cent in New Orleans medical students to 85 per cent as found by Legge, Bonar and Templeton² in the University of California. The latter investigators found 53 per cent of the newly entered men students to be infected.

During the spring of 1932 we examined 500 consecutive men students taking the regular prescribed gymnasium course. At the same time we examined 285 women students. As the results in the two groups were surprisingly similar, 60 per cent positive cases among the men and 57 per cent among the women, the results among the men will alone be analyzed.

The group of women students represented those taking swimming in addition to gymnasium work. These students were examined in a manner similar to the men students. In addition, a smaller group was examined both before and after the swimming period in order to test the effect of chlorinated water on the fungus between the toes.

All the men students had attended at least four months of gymnasium work, with an average of about one and one-half years. The average age of the student was 19½ years. Less than 2 per cent were foreign born, and 56 per cent lived at home. A preliminary questionnaire was filled out, giving such data as age, class, college, residence, rooming conditions, contacts and general hygiene. The students were further questioned concerning any symptoms referable to the feet—particularly sweating, itching, soft corns and plantar warts. Inquiry was made concerning any present or previous type of ringworm infection that may have been associated. Previous treatment was recorded when stated.

The status of the feet clinically was noted as "clinically negative" or "borderline," or else described as chronic exfoliative type, macerative, hyperkeratotic or acute vesicular, as the case might be. The extent of the process was noted, as well as any evidence of ringworm elsewhere on the body.

Scrapings were taken from all available areas involved on the feet, as abundant an amount as possible was taken. Part of the material was examined directly under the microscope, the caustic potash technic being used. Another portion was planted on a tube each of Pennsylvania medium (a modified Sabouraud medium) and conservation agar.

Read before the thirteenth annual meeting of the American Student Health Association, New York, Dec. 29, 1932.

² Legge, R. T., Bonar, Lee, and Templeton, H. J. *Incidence of Foot Ringworm Among College Students J. A. M. A.* 93:170 (July 20) 1929. *Ringworm of the Feet ibid.* 92:1507 (May 4) 1929.

Of the 500 students examined, 297 (60 per cent) had gross evidence of ringworm. Most of these cases were either borderline or of the chronic exfoliative type. Acute vesicular cases were unusual, probably explained by the season of the year (January). There was evidence of associated ringworm lesions but sixteen times in this group—surprisingly small. The most common additional involvement was tinea cruris with involvement of the scrotum. Infections of the hands and nails, and the presence of plantar warts were rare complications. Soft corns appeared but twice in contradistinction to the findings of Hulsey and Jordan,³ who conducted a more limited survey among our medical students in 1925.

Clinically the most outstanding symptom among these students was the occurrence of immoderate foot sweating—an increase of 50 per cent over the noninfected group. We found, too, that sweating appeared to have a marked deterrent effect not on the causation of ringworm but on the laboratory confirmation of what was an apparent bona fide clinical type. Previous treatment was effective mainly in making the cultural confirmation difficult.

TREATMENT AND CONTROL

The management of ringworm of the toes has become unnecessarily involved and complicated. This is largely due to the widespread publicity given to it as "athlete's foot" and the multitude of sure-cure applications offered to both the medical profession and the public. The fact that a number of these infections will respond to almost any agent employed does not tend to rationalize a proper therapy. Consistently good results can be obtained by following a simple treatment in accordance with a few general rules. At least one can avoid the mistake of overtreatment.

If one considers ringworm of the toes in its stages or in its status as a form of dermatitis, acute or chronic, one can treat on morphologic principles and obtain a rather prompt response. I do not believe there is any one specific for ringworm, despite the success *in vitro* of such chemicals as certain of the dyes, volatile oils, and organic acids. Proper foot hygiene, that is, the frequent changing of shoes and socks and the thorough drying of the toes after washing, is the first consideration. Then the use of wet compresses or antiseptic soaks, followed by the use of ointments either bland, stimulating or keratolytic, is in order. Finally, one has recourse to stronger lotions and powders in the chronic type of infection.

The acute, moist and vesicular type, often with a superimposed pyogenic infection, demands the most careful choice of bland applications, and it is this type of case that so often may be overtreated by the enthusiastic proponent of salicylic acid. The chronic or carrier stage may respond to any irritating antiseptic, or at least can withstand any amount of home remedies. X-rays help materially in shortening the course of the infection, but a long series of roentgen treatments serves no good purpose, does not permanently cure, and should be avoided. In the Student Health Service we have not had recourse to either quartz lamp or x-rays, and our results are comparable to those I obtain in dispensaries in which these modalities are available.

There are some complications attendant in a small proportion of the cases that make their management a problem indeed. I refer to those cases of acquired sensitization both to their ringworm infection and some

other allergen, and to the susceptible patient who develops a sort of systemic dermatophytid. There are likewise certain individuals who have an extremely difficult time in combating the combined pyogenic-fungal infection. In this group one may go to great lengths in the systemic and dietary investigations, with treatment prolonged and arduous.

For compresses or soaking foot baths in the acute stage, I use saturated solution of boric acid or Burow's solution, 1:16. For the subacute (and in some acute cases), potassium permanganate, 1:4,000, has no equal. I prescribe this in the form of a hot foot bath, fifteen minutes before bedtime. The soaks or compresses are followed in the acute cases by a 5 per cent ointment of ammoniated mercury applied in and around the toes after they have been thoroughly dried. The progressing or subacute case does better on a mildly stimulating tar ointment, either a 6 per cent crude coal tar, or a 3 to 5 per cent pine tar. If all signs of acuteness have subsided, then I employ the well known Whitfield ointment, using the 3 per cent salicylic acid and 6 per cent benzoic acid strength. In the chronic stage with either maceration or fissures, the alternate use of a strong stimulating tar and Whitfield's ointment is in order. It is also in this type of case or the carrier stage that the volatile oils and dyes find their greatest usefulness. I use mercuriochrome solution in the mildest types, and a solution of basic carbol-fuchsin (Castellani) for the more resistant case. An alcoholic solution of 4 per cent salicylic acid and 8 per cent of resorcinol applied to the toes, or a foot powder used in the daytime, is helpful in those cases associated with excessive sweating. Cleanliness, dryness and debridement constitute the physical measures necessary, and, in some chronic calloused types, resort must be had to the use of pumice stone or sand paper.

The practical features of control have been elaborated on elsewhere and to a good advantage, so that at the present time practically all student health services have instituted some form of antiparasitic foot baths in which use is made of sodium thiosulphate, hypochlorite solutions or formaldehyde. In addition, gymnasium directors are seeing that the locker floors and runways are scrubbed down with the solution selected. The factors in this regimen include a choice of chemical which in an effective dilution is nonirritating to the feet and which is of sufficient strength to work with some degree of effectiveness within a minute's time. Perhaps it is not so much the direct immersion of the feet that is important as the natural tracking of the solution about the locker room floors. In addition, the foot baths must be strategically located so that it is difficult for the student to avoid their use.

Another important method in control is the effective fumigation of apparatus when necessary. It is well known that boxing gloves constitute a menace in the dissemination of pyogenic infections as well as molluscum contagiosum and the less common ringworm of the face. In some gymnasiums—more often the private ones—paper slippers are used. It has been shown by Dr. Spring that the ordinary chlorination of the swimming pool has no merit in the prevention of the spread, as exposure in the pool of over an hour and a half is without effect.

Prevention or prophylaxis *per se* is not within our scope, as such a large number of infections are found among entering students, but it is our duty to control and minimize its spread. If the work of Osborne and

Hitchcock⁴ in Buffalo and of Gould⁵ in Albany is taken up in the secondary schools with the popularity that it deserves, there should shortly be a lessened incidence in freshmen, and this must not find physicians unprepared to work toward the reduction of reinfection

1930 Chestnut Street

ELECTROGALVANIC LESIONS OF THE ORAL CAVITY PRODUCED BY METALLIC DENTURES

EVERETT S. LAIN, M.D.

Professor of Dermatology and Radiology, University of Oklahoma School of Medicine

OKLAHOMA CITY

In a previous communication I¹ discussed lesions of the oral cavity caused by electrogalvanic discharges between dissimilar metallic dentures and reported thirty consecutive cases measured for electric current. Since that time I have been privileged to make a careful study of more than 300 additional cases which contained various dissimilar metallic dentures. From this study, I feel justified in forming certain definite conclusions.

I have confirmed, by repeated experiments, that human saliva, whether acid, alkaline or neutral, makes a good electrolyte through which metallic electrons freely circulate from a higher to a lower electropotentiality. Thus within every oral cavity which contains dentures such as plates, bridges, crowns, or fillings of dissimilar elemental consistency, there is constituted a complete galvanic battery.

This newly discovered oral cavity phenomenon is in keeping with a fundamental law of electrophysics discovered by Galvani in 1786—later verified by Volta—which declares that when dissimilar metals (electrodes) are brought into association through a suitable liquid medium (electrolyte), there takes place a disturbance in their equilibrium and a disassociation of their elemental electrons. The electrons of a higher or electropositive position in the electromotor series of metals flow toward and replace or repose on those of a lower or electronegative position. This exchange of electrons between metallic dentures within the oral cavity is a continuous process and after a time may become manifest by both objective and subjective symptoms.

SYMPTOMS OBJECTIVE AND SUBJECTIVE

Objective electrochemical changes that take place in metallic dentures consist of discoloration, areas of erosion, disintegration or perhaps a loosening of fillings or crowns and a possible maladjustment of plate dentures.

Objective symptoms of the oral tissues consists of acute or chronic inflammatory, blanched or grayish patches, erosions or ulcers. After a time, leukoplakia may appear on the gingival or buccal membranes beneath adjacent to or surrounding the metallic dentures. Many times erosions, ulcers or leukoplakia occur directly beneath or beside the offending denture and the cause is so obvious as to be rightly designated

"galvanic burns."² An occasional case of metallic pigmentation of the mucous membranes has been observed.

Subjective symptoms consist of an intermittent astringent, metallic or salty taste and a burning or stinging sensation of the margins, the end or sometimes the base of the tongue. Many patients complain of a dryness or tickling sensation in the throat. Approximately 80 per cent of the patients have an increased salivary secretion. Such symptoms are more perceptible in the early morning after the mouth has been closed for a long period and the stomach has become relatively empty.

When two dissimilar metal dentures happen to come in contact, there frequently occurs a nerve soreness or an occasional electric shock. Dentists have for many years recognized this possibility and have made a practice of grinding short one of the metallic contacts.

Dental cements that contain a high percentage of zinc are electropositive to gold and capable of causing trouble, likewise there is an electric current between dissimilar amalgams.

Very few of the subjective symptoms are continuous and may, after a time, like the taste of a new drinking water, become gradually tolerated. However, some patients progressively become nervous, suffer with stomatitis, indigestion and loss of weight, and perhaps eventually may develop symptoms of general debility. They often pass from one dentist or physician to another seeking relief.

Cases in which a full upper or lower denture made of aluminum or zinc is worn in association with another containing clamps or structures of gold, or metals of radically different electropotentiality, present the most striking and serious disorders. Such radically incompatible dentures may eventually produce pathogenic changes in the blood and kidneys and cause hyperplasia and leukoplakia of the soft tissue, which may finally become malignant.

Such pathologic changes produced by the electrogalvanic current may be, on casual inspection, indistinguishable from lesions produced by infections, tobacco, or traumatic injuries from rough teeth or dentures. Anemias, syphilis, lichen planus, lupus and other diseases—likewise, drug eruptions—which frequently occur on the oral tissues must first be eliminated before a positive diagnosis of electrogalvanic phenomena is made. The excessive use of tobacco, acid foods, or the presence of bacterial infections perhaps in certain cases serves to augment electrogalvanic injuries.

FACTORS INFLUENCING ELECTRIC CURRENT

The intensity of the electric current and its potential dangers depend on many factors:

1. Total surface or volume of the dissimilar metals.
2. Chemical variation of the saliva. Hyperacidity or hyperalkalinity perceptibly increases the amount of current generated.
3. Resistance of tissues and distance between dentures. Tissue resistance is lowered and sensitivity increased in the presence of infection, also the distance between dentures apparently tends to increase rather than decrease the electric units. Such seeming contradiction of a fundamental law of electricity is probably due to a less rapid drawing or exhaustion of current between dentures that are more widely separated.
4. Duration, that is, time since the restoration of the first and the subsequent dissimilar dentures. Acuteness

or chronicity of an irritant may determine the type of lesion present. An electric discharge registering but a few micro-amperes, like the dripping of water on a stone, though at first imperceptible, may eventually produce changes of a gross appearance.

5. Relative position of the metals in the electromotor series. This is the most important factor that determines the intensity of the current. For example, only three positions in the electromotor series separate pure silver and pure gold, therefore, only a few degrees of current are generated by amalgams of a high percentage of silver with that of an associate high percentage of gold. In contrast, there is a difference of nineteen positions between aluminum and gold, and seventeen between zinc and gold, therefore, the association of such dentures produces the most serious injuries of the oral mucosa and the gravest constitutional symptoms.

I have observed two cases in which marked pathologic changes in the mouth and severe constitutional symptoms were present. Each of the patients was wearing a full upper denture made of aluminum with a lower denture made of gold, between which there was a current flow of from 80 to 100 micro-amperes.

TABLE 1—Metals in Electromotive Force Series³

Positive End	Negative End

Berium	Copper
Strontium	Arsenic
Calcium	Bismuth
Magnesium	Antimony
Aluminum	Mercury
Manganese	Silver
Zinc	Palladium
Chromium	Platinum
Cadmium	Gold
Iron	

METALLIC DENTURE MATERIAL

Restorative amalgams consist of three or more of the following metals: silver, tin, zinc, copper, and sometimes gold or platinum, to which is added mercury to produce the amalgamation. One popular brand of amalgam is advertised by its manufacturer as containing silver, 67 per cent, tin, 29 per cent, copper 3.5 per cent, and zinc, 0.5 per cent.

Gold denture material is alloyed with one or more of the following metals: copper, nickel, silver or platinum. Gold used for crown and bridge work varies from 75 to 91 per cent pure, to which has been added from 8 to 15 per cent of copper to give hardness, and a small percentage of silver, nickel or platinum to give color and strength.

MEASURING THE CURRENT

During my measurements of electric currents in the oral cavity, I have tried various instruments, though I have found the Weston direct current micro-ammeter number 320 the most reliable and convenient. Connecting cords consist of flexible number 18 copper-corded wires covered with heavy soft rubber. Contact electrodes consist of angular hard rubber handles through which run solid copper wires pointed at contact ends.

Measurements should first be made with the mouth open. The contact points are cleansed with 70 per cent alcohol. The electrode connecting with the positive

side of the micro-ammeter is placed in contact with the gold or with that denture which belongs to the negative side of the electromotor series of metals. The electrode connecting with the negative side of the meter is placed in contact with the other denture which is in a higher position or positive side of the electromotor series. The meter needle at once ascends to its highest reading and then slowly returns to a level at which it stands for a short period. With the mouth open the dentures soon become dry, polarization of electrode points occurs, the density of the electrolyte is reduced, and current is withdrawn from the metals being tested. These factors cause a slowly diminishing current until it soon reaches zero.

For scientifically accurate measurements, other factors such as the ohms of resistance, both in the mouth and in the instrument used, must be considered. The resistance of the instrument I have used is 8 ohms. The resistance between dentures in the oral cavity varies from 10 to 30 ohms.

The millivoltage or unit of pressure may be approximately calculated by multiplying the micro-amperage registered by the sum of the ohms of resistance in the instrument and in the mouth.

Millivoltage may be accurately measured by a special type of galvanometer so designed as to draw an imperceptible amount of current from the metals tested.

REVIEW OF LITERATURE

Lippmann⁴ of Hamburg has reported two very striking cases: one patient had been wearing a plate denture made of zinc, the other, a plate made of Randolph metal. Each had suffered severely with both local and general symptoms of metallic toxemia. They both made a complete recovery when the dentures were removed and like metallic dentures were substituted. These cases were more fully reported in my previous paper¹.

Hollander² has reported three cases which he diagnosed as electrogalvanic burns of the oral mucosa. In each the common symptom of metallic taste and general discomfort in the mouth were present. One case was made worse by the taking of hydrochloric acid. Two patients had painful ulcers in the mouth which resembled aphthous stomatitis. The symptoms in one of the patients just mentioned became worse just before menstruation, one had whitish-gray patches adjacent to and opposite a large gold bridge. Routine laboratory tests were negative. The removal of an offending denture in each case gave complete relief. In one case a recurrence of the trouble occurred immediately on replacement of the original denture.

Karl Ullmann⁵ of Vienna, at a meeting of the Vienna Medical Association, April 15, 1932, gave a general discussion of lesions of the oral cavity. He applied his remarks to lesions caused by the electrogalvanic current, relating the history and symptoms in nine cases. As proof of his diagnosis, complete recovery occurred in each after removal of the dissimilar and the replacing with uniform metallic dentures. A brief abstract of his address follows:

I shall make a report concerning a new form of leukoplakia which has not hitherto been described. I wish to designate this condition as leukoplakia galvanica or electrogalvanica.

⁴ Lippmann, A. Disorders Caused by Electric Discharges in the Mouth in Artificial Dentures, *Deutsche med. Wchnschr.* 56: 1394 (Aug. 15) 1930.

⁵ Ullmann, Karl. Leukoplakia Caused by Electrogalvanic Current Generated in Oral Cavity, *abst., Wien Klin. Wchnschr.* 45: 840 (July 1) 1932.

³ Hodgen, J. D. *Practical Dental Metallurgy*, ed. 7, St. Louis, C. V. Mosby Company, p. 49.

Such lesions arise on various portions of the mucous membrane of the oral cavity, as I shall herein show by illustrations. They appear on the tip, edges and dorsum of the tongue, or they may occur on the muscles of the mouth, the tonsils, the gums and the soft palate as white to grayish, smooth and sometimes raw plaques, also, I have seen two cases of striplike abnormal pigmentation of the gingival or buccal surface. They are localized areas, in most cases unequally distributed. Biopsy shows no deviation from the normal tissue except increased cellular formation and hyperkeratosis, while between the individual cells are formed also normal cells of an inflammatory nature with eleidin content.

This leukoplakia is invariably accompanied by subjective symptoms such as metallic taste, especially during morning hours when the stomach is relatively empty, a loss of appetite, an indefinite, peculiar, burning sensation, and, finally, inflammation and erosive patches in strandlike formations.

He further remarks

I have frequently observed such inflammatory changes in the oral cavity and was unable to explain them until I read the explanation given by Lain of Oklahoma, in the January, 1932, issue of the *Archives of Dermatology and Syphilology* in which Lain describes the interdependence of stomatitis and leukoplakia and the physiochemical processes involving the cause of such condition.

Dr. Ullmann further declared that he had proved by micro-ammeter tests made of dissimilar metals in the mouth that electrogalvanic currents do exist and that he had verified his diagnosis and the etiology of such by differentiating laboratory tests, including removal and replacement of the dentures. Without other treatment he then observed a disappearance of both the erosions and the leukoplakia.

Dr. Ruth Friedlaender⁶ of the Post-Graduate Dental School, University of Hamburg, during research on her graduate thesis, examined and made records of a total of seventy-six patients whose mouths contained dissimilar metal dentures. In six cases of this series she was able to control absolutely the electrogalvanic phenomena, in the positive cases by the removal and replacing of the offending dentures. Her statistical summary revealed that 56.6 per cent gave positive symptoms of various electrolytic processes and disorders. 39.3 per cent showed no such evidence at the time of examination, 3.9 remained questionable cases of mechanical rather than electrolytic effects.

REPORT OF CASES

The following reports of cases were selected from my file of more than 300 cases, to illustrate the more common objective and subjective symptoms.

CASE 1—Mrs. C., aged 32, had two large amalgam restorations in the lower right side of the jaw with no discomfort until after a large gold filling was placed in an upper right tooth opposite the amalgams. Immediately after, she began to suffer with electric nerve shocks when the upper gold and lower amalgam came in contact with each other. The shock at times was so severe as to cause her to cry out with pain. Her dentist ground short the gold denture, but contact on mastication still caused shock. Examination showed tender inflammatory patches on the buccal surface exactly opposite the restorations. Measurements registered 38 micro-amperes. Saliva was 2 plus alkaline. After removal of the amalgams and restorations of similar gold the nerve shocks ceased, the mucous patches healed, nervousness was allayed and general improvement in health followed.

CASE 2—Mrs. H., aged 43, had two amalgam fillings in the lower left side of the jaw for many years with no trouble.

Two years ago she had a gold bridge placed in the upper left jaw and three gold restorations in the right lower jaw. She immediately noticed a metallic taste and increased salivary flow. Later, the tongue felt irritated and became eroded on the right side. She became nervous and suffered from indigestion, loss of sleep and weight. Examination revealed inflammatory patches over the buccal, palatal and gingival surfaces. Measurements between dentures registered 18 micro-amperes. Saliva was 1 plus acid. Removal of the amalgam fillings gave partial relief. Removal of all the gold gave complete relief. Later, she had gold restorations testing approximately the same electropotentiality and has since enjoyed perfect health.

CASE 3—Mrs. J., aged 38, had several amalgam fillings in lower left molars for many years without trouble. Within a few days after the installation of a gold bridge in the upper jaw she began to have a peculiar mineral taste, with irritated margins of the tongue, and salivation. She occasionally experienced electric nerve shocks when the upper and lower

Experiment 1 (With Buffered Solution)	Micro-Amperage	
	Initial	Steady
pH 5.2 (acid)	210	140
pH 7.2 (alkaline)	200	135
pH 7.0 (neutral)	170	110

fillings made contact. One of the fillings was ground short, reducing the nerve shock, although the tooth continued to cause discomfort. A roentgenogram of this tooth was negative. Measurements of the dissimilar dentures registered 50 micro-amperes of initial current. The saliva was 2 plus alkaline. Removal of the amalgams gave relief. Restorations with gold were made which tested the same electropotentiality, and she experienced no further trouble.

CASE 4—Mr. H., aged 50, had been wearing for five years an upper plate made of aluminum and vulcanite with a setting of two gold crowns. He felt no discomfort until soon after the extraction of several lower teeth and the substitution of a partial vulcanite and gold denture. He immediately noticed a metallic taste, increased salivation, burning tongue and inflammatory patches and erosions over the hard palate. All symptoms grew worse until there were observed horny proliferating growths over the hard palate resembling early cancer. He obtained partial relief at night by removal of the upper plate. Soon after the lower denture was made, there occurred multiple pitlike disintegrated areas over the basal surface of the aluminum plate. This phenomenon was also observed around the gold crowns. He tested 92 micro-amperes. Saliva was 2 plus acid. After the aluminum had been discarded and a replacement with uniform dentures had been made the growths slowly disappeared, he became free of all subjective symptoms and his general health improved.

⁶ Friedlaender, Ruth. Electrolytic Manifestations in the Oral Cavity in the Presence of Two or More Metals. *Zahn. Abw.* Aug. 15, 1932.

CASE 5—Mrs. H., age 60, had a gold bridge on the lower right side, which she had worn with comfort. She recently had a restoration with a gold inlay and gold crowns on the left side. At once she began to experience a peculiar taste, salivation and irritated margins of the tongue. Later the margins of her tongue became eroded, she became nervous, had indigestion, and began to lose sleep and weight. Examination showed also an enlargement of the circumvallate papillae at the base of the tongue and a marked discoloration of one of the gold dentures. This was polished and local treatment was instituted with only a slight improvement. Saliva was 2 plus acid. Measurements between the gold dentures gave a reading of 18 micro-amperes. Removal of all dentures was soon followed by complete relief of subjective symptoms and healing of erosions. Later, gold dentures testing approximately the same micro-ampere in buffered acid solution were placed in the mouth. Her general health improved and marked gain in weight was recorded.

SUMMARY AND CONCLUSIONS

1 A study has been made of more than 300 oral cavities which contained dissimilar metallic dentures, 71 per cent of which showed some evidence of electrogalvanic phenomena.

2 The human saliva is a good electrolyte and dissimilar metallic dentures constitute the necessary electrodes, therefore, within every oral cavity containing dissimilar metallic dentures there is a complete galvanic battery.

3 The intensity of the current and the pathologic changes produced depend on many physical and electrochemical factors. The most important is the relative position of the dissimilar metallic dentures in the electromotor series.

4 The most common objective and subjective symptoms produced are metallic taste, salivation, mucous patches, erosions, leukoplakia, nerve shocks, burning tongue, indigestion and nervous irritability. Each of these symptoms may be more or less intermittent.

5 Positive cases of electrogalvanic injuries are promptly relieved by removal of the offending dentures and restorations with dentures that are of uniform electropotentiality.

6 A recent survey of 150 consecutive cases in which dentures had been changed since the first examination revealed that 56.1 per cent resulted in complete relief, 32.8 per cent in only partial relief, and 11.1 per cent in no apparent relief since the change. Of the patients having only partial or no relief, several have been reexamined and found to have dentures still of unlike electropotentiality.

7 In order that the electrogalvanic phenomenon with its serious pathologic changes in the oral cavity may be avoided, manufacturing dental laboratories should endeavor to offer to the profession satisfactory denture materials that are of the same electropotentiality.

SPINAL FLUID CELL COUNT AND ENCAPSULATION OF BRAIN ABSCESS

AN ATTEMPT TO CORRELATE THESE FACTORS, AND TO DETERMINE THE OPTIMAL TIME FOR DRAINAGE

HENRY W. WOLTMAN, M.D.

ROCHESTER, MINN.

In every case of abscess of the brain a twofold responsibility is thrown on physicians. First, the condition must be recognized, if possible when it exists, mistakes are brought home at necropsy and one learns to do better. Second, the right thing must be done at the right time, this is much more difficult, of blunders one is often unaware, and unwittingly they are laid to the will of God. In a valuable paper on this subject, Grant¹ stated "Drainage of a brain abscess before

Chart 1.—Degree of encapsulation and cell count of spinal fluid series with necropsy (eighteen cases)

encapsulation has occurred has been uniformly disastrous in our experience. Only two patients died because operation was delayed too long."

I should like to dwell briefly on this question of the optimal time for drainage of an abscess of the brain, which was called to my attention by Adson² and by Lillie,³ and to raise the question whether the cell count of the spinal fluid may help in directing the course one should pursue.

Until recently the practice has been to operate as soon as a diagnosis of abscess has been made. It might be well to examine this dictum in the light of the pathologic processes that come into play. Macewen⁴ and other investigators well described the development of an

abscess, and Lund,⁵ particularly, has dealt with these changes as reflected in the spinal fluid. The typical course of the commonest variety of surgical abscess, the otogenous variety, may serve as an illustration. Invasion of the nervous system is usually marked by abrupt onset of signs indicating meningeal irritation, a shower of neutrophilic cells in the spinal fluid accompanies this. If the date of this occurrence can be determined, it is helpful indeed. Such a history may be lacking when the subarachnoid space has escaped more general invasion. Then follows invasion of the brain itself, and encephalitis, or cerebritis, results. While this is going on the cells in the spinal fluid diminish in number, and the neutrophils are superseded relatively by lymphocytes.

The progress of encephalitis varies greatly in tempo and in extent. The process of defense generally begins at once, and a barrier of lymphocytes, connective tissue and glial cells is built up, thus starting the process of encapsulation. At this time a diagnosis of abscess is often made and operation instituted. The needling results in dissemination of the infection, and the post-operative course is usually stormy. The immediate indication requires courage and is the hardest step to carry out, it is to wait. In doing so, liquefaction and relative sterilization of the contents take place, a better capsule is formed, and immunity is added to the defense of the patient, which he will need later. But if one waits too long, the abscess may extend anew or rupture, or the patient may suddenly die of respiratory failure. Between these two extremes lies the best time for drainage.

The means for determining this optimal time are limited. It is seldom as early as two weeks, and often as late as six weeks after the period of invasion. If the optic disks are choked, a valuable source of help is at hand. The safest time for drainage, as Lillie has observed, is when choking has attained its maximal degree and the disks have become quiescent. Often however, and this varies greatly with the source and the site of the abscess, choking does not occur and one must look elsewhere for help.

This may be found in examination of the spinal fluid. Study of the cells is apparently the most fruitful source of information. Unfortunately, spinal punctures were made in only 36 of 161 cases in which the diagnosis of abscess of the brain was verified. This series is too small and the data obtained are not entirely convincing. That so few punctures were made was largely due to the fear that puncture might lead to rupture of the abscess. I am convinced that this danger has been overrated and I have twice witnessed rupture of a ventricle into an abscess cavity at the time of drainage when the pressure of the cerebrospinal fluid on the

opposite side of the wall alone could account for it. Gardner⁶ has expressed a similar view, he does not hesitate to perform spinal punctures or to make encephalograms if abscess of the brain is suspected.

In chart 1, the cell counts of the spinal fluid have been tabulated parallel with the degree of encapsulation, as determined by a study of the gross specimens and the microscopic preparations. The cases are arranged according to the completeness, thickness and toughness of the capsule, graded on a basis of 1 to 4. A glance at the chart as a whole reveals that the better the encapsulation, the smaller the number of cells in the spinal fluid. It will also be noted that, in three cases in which the wall of the abscess impinged on the ventricle, the cell counts in two were rather high and the neutrophils well represented. In another case the neutrophils far outnumbered the lymphocytes, the cell counts being respectively 395 and 8. The neurologic complication had begun two months previously. At operation 2 ounces (60 cc) of pus was drained from the abscess cavity. The patient did not improve as it was hoped she might. At necropsy it was found that the capsule

Chart 2—Cells for each cubic millimeter of spinal fluid surgical series solid areas lymphocytes shaded areas neutrophils

of the abscess was poorly formed and that there was coexisting acute ependymitis and encephalitis, operation would not have helped at any time.

In two cases, listed separately, the abscesses had ruptured, but in one of these there had been no hint of rupture, and since abscess still dominated the clinical picture, this patient was referred for operation. The inference is that when neutrophils exceed lymphocytes in the spinal fluid, too much must not be expected from surgical intervention.

The mere presence of neutrophils, however, does not preclude a favorable outcome, this is illustrated in the left hand column of chart 2. The reader should not be led to infer that the appearance of fatal and nonfatal cases on the same chart in the surgical series represents the surgical mortality. The cases that ended fatally usually presented greater difficulties in diagnosis, so that a proportionately greater number of punctures was made in these.

⁵ Lund, H. *Acta Otolaryng.* 11: 479-522, 1927.

⁶ Gardner, W. J. Personal communication to the author.

Two cases of so-called pseudo-abscess are included in chart 2. Here there was a clinical picture of abscess, pathologically there was at least a partial capsule but there was no liquefaction, obviously operation was not required. These, as may be seen, had high neutrophilic cell counts.

COMMENT AND SUMMARY

Abscess of the brain presents a highly varied clinical panorama that cannot be reduced to a simple formula. Each case is a law unto itself. The problem calls not only for a diagnosis but also for decision as to when the abscess shall be drained. Awaiting the optimal time means a better capsule and a liquefied interior, and consequently better drainage, it means less virulent organisms and greater immunity, and hence less danger to the patient.

The risk of performing spinal puncture in cases of abscess has probably been overrated, and thus physicians have been deprived of information that might be helpful.

After invasion of the brain has taken place and the formation of an abscess gets under way, the number of neutrophils in the spinal fluid becomes absolutely and relatively reduced.

The persistence or reappearance of neutrophils suggests that encapsulation is not progressing favorably.

An appreciable number of neutrophils may indicate extension of the abscess or close proximity of the abscess to the ventricle.

A predominance of neutrophils in the spinal fluid was seen in cases in which operation was performed unnecessarily or which ended fatally.

A small number of lymphocytes would seem, on the whole, to indicate better encapsulation, greater resistance, and a smoother convalescence after operation.

PERSISTENT DERMATITIS

AN UNUSUAL SEQUELA OF RADICAL OPERATION FOR TRIGEMINAL NEURALGIA

E. W. NETHERTON, M.D.
CLEVELAND

Modern neurologic surgery has decreased to a negligible factor the mortality following radical operations for major trigeminal neuralgia. Improvement in the technic of operative approach has decreased the complications and undesirable sequelae so materially that a person suffering from this distressing condition need have no hesitation in submitting to this operation. However, for the past two years I have observed a patient who developed an unusual condition following operation on the gasserian ganglion.

REPORT OF CASE

A married woman, aged 41, came to the clinic, March 13, 1930, because of a pain and a burning sensation on the left side of her face. She was from a family of ten children, two of whom had died from epilepsy. Otherwise there was nothing of significant interest in the family history. She had had measles, mumps, scarlet fever, whooping cough, tonsillitis and influenza. She gave a history of having had attacks of urticaria and at times had developed a mild, flexoral eczema. She had been married eighteen years and had two children.

The pain of which the patient complained was noticed first in December, 1925. A hot, jagging sensation occurred in

paroxysms lasting from a few seconds to a minute, and during the intervals the patient was free from pain. The pain was on the left side only, involving the upper lip, corner of the mouth, molar region, forehead and anterior portion of the scalp. Talking, chewing and sudden movements of the head and face precipitated the attacks. Definite trigger points were present on the upper lip and lower eyelid. The attacks occurred many times a day. Several teeth had been extracted and an operation on the left maxillary sinus had been performed, however her condition had become progressively worse. A diagnosis of major trigeminal neuralgia was made by Dr. W. J. Gardner of the neurosurgical division.

March 14, a subtotal resection (Frazier's method) of the sensory root on the left fifth cranial nerve was performed by Dr. Gardner. The motor root was left intact, but a few fibers of the third division were sectioned. Complete avulsion was done in the first and second divisions. The patient's postoperative course was uneventful. She was completely relieved of pain but complained of numbness. There was no keratitis or other eye complication. She remained in good health until March, 1931, at which time a red spot appeared on the left side of her forehead. This erythematous plaque gradually enlarged until it involved the left side of the forehead, the left temple region, the upper left eyelid and the left side of the nose and cheek. The lower eyelid and adjacent skin remained clear. The skin near the left corner of the mouth also became involved. There was a very sharp demarcation of the margin of the plaque in the midportion of the face but this was less marked elsewhere. At no time were there any subjective symptoms or infiltration of the skin. The plaque had the clinical appearance of simple dermatitis except for the sharply defined central demarcation.

Examination revealed hypesthesia in the areas supplied by the first and third divisions of the left fifth cranial nerve and anesthesia to pin prick over the second division. The left corneal reflex was absent and the sensation to pain was lacking in the conjunctiva of the left eye.

The eruption would almost disappear or become inconspicuous for four or five days at a time. Exposure to heat, cold, wind, soap and water made the condition very noticeable. At times the plaque became very red and weeping. As the acute reaction subsided, a small, dry, adherent scale developed. Vesicles never were observed. Thermocouple readings showed no difference in the surface temperatures of the normal skin of the right side of the forehead and of the involved area on the left side. Unfortunately, a biopsy was not obtained. Various local applications failed to give relief. When the patient was observed in April, 1932, there had been no material change in her condition. There had been no dermatitis nor skin eruption on the right side of the face.

COMMENT

A search through the cumulative index and a review of some of the writings of prominent neurologic surgeons revealed that cases similar to the one here described are extremely rare.

In 1925, Becker¹ gave a good review of the literature and discussed the theories of the etiology of trophoneuroses following nerve injury. He also reported a case observed at the Mayo Clinic which was practically identical with the case described here. A woman, aged 47, had an eczematoid dermatitis on the right side of the face, three weeks after section of the posterior root of the right trigeminal nerve. At no time did the lesion appear to be herpetic. Previous injections of osmic acid and alcohol had not been followed by a similar sequela. There was complete anesthesia of the areas involved. Various topical applications failed to give permanent relief.

Herrick² recently reported a case of eczematoid dermatitis which developed on the forehead near a scar

From the Cleveland Clinic.
This case was presented at the Annual Meeting of the Four Cities Dermatological Society in Cleveland, in 1931, but was not reported in the society proceedings.

produced by an injury received in an automobile accident. The eruption was limited to the area supplied by the supra-orbital branch of the fifth nerve. This was considered strong evidence that the eruption was of nervous origin. Various forms of treatment were not beneficial.

In all cases of eczema following nerve injury which Bruck³ reviewed, the eruption developed on the side of the injury. The case which he reported differed in that the dermatitis was limited to the side of the body opposite to the injury. His patient was a man, aged 38, who was shot in the face during the war. The bullet penetrated beneath the left zygomatic arch and remained lodged in front of the right auditory canal beneath the skin, being removed later by an operation. The right facial and trigeminal nerves were paralyzed. Eight weeks later a papulovesicular dermatitis developed over the entire left side of the face and neck. However, there was not a sharp demarcation of the eruption in the midportion of the face, and the right side of the neck was involved but to a lesser degree than the left side. Treatment gave only a temporary relief.

The vasoconstriction tests with cutaneous application of epinephrine, as in the Pirquet reaction, gave a completely negative reaction on the right side of the face, while the anemic focus appeared distinctly on the left side. There was a vasomotor response to scratching on the left side of the face, but this was absent on the right. Only the areas with disturbed vasomotor irritability due to nerve injury were spared. Bruck expressed the opinion that such observations support Krehlich's theory of the neurotic origin of eczema and advised that dermatologists keep in mind the necessity for observing more closely the relationship between nerve damage and eczema.

Adson⁴ reviewed 839 cases of trigeminal neuralgia examined and treated at the Mayo Clinic. Operation was performed in 587 cases. He mentioned paresthesia, keratitis, iritis, conjunctivitis and ocular palsy as the most frequent complications. He did not include herpes or a condition similar to that in the case just reported. Frazier's⁵ observations are similar to those of Adson, but he stated that an herpetic eruption on the face and buccal cavity, usually involving the distribution of the maxillary division, may appear on the second or third day following operation for major trigeminal neuralgia. He has pointed out that, by conserving the ophthalmic division of the fifth cranial nerve in the operative treatment of trigeminal neuralgia, trophic keratitis has ceased to be a troublesome sequela.

The experience of the neurosurgical division of the Cleveland Clinic in cases of trigeminal neuralgia was reviewed by Locke⁶. He did not mention any such trophic disturbance of the skin. Cushing⁷ has

observed cases in which herpes followed operation for trigeminal neuralgia. The lesions appeared on the lips and nose on the side of the operation. In other publications on trigeminal neuralgia he has not mentioned sequelae similar to those seen in the patient here described.

Peet⁸ reported two cases of postherpetic trigeminal neuralgia, one of which was somewhat similar in that the skin over the right forehead, cheek and nose was reddened, dry and scaly, with many white scars, one year following the herpes. At operation the right gasserian ganglion was pinker than normal and the sensory root was similar in color to normal muscle. An operation gave little relief of the pain, and no statement was made concerning the subsequent changes in the condition of the skin.

Since in the case I have described the eruption did not appear until one year following the operative procedure, some doubt may be raised as to the accuracy of ascribing this as the cause of the complication. However, even though there was no evidence of keratitis it has been impossible to account for this skin eruption except on the basis of some neurotrophic disturbance. The striking feature of the eruption was its limitation mainly to the area involved in the avulsion of the second and first divisions. This, and the absence of characteristics of any of the more common dermatoses, seems to justify the conclusion that the eruption was related to the operation.

Clinically, the appearance of the eruption was that of a permanent flush with periodic exacerbations of an exudative inflammation. These exacerbations frequently followed exposure to heat, cold, wind, and the use of soap and water and, as would be expected, were not accompanied by subjective symptoms. The patient was observed several times over a period of one year and at no time was there any involvement of the right side of the face. Likewise there were no vesicles suggestive of herpes. The sharply demarcated margin in the central portion of the forehead and on the nose did not change. Factitious dermatitis, lupus erythematosus, seborrheic dermatitis or dermatitis venenata could be eliminated easily in the differential diagnosis. The absence of infiltration as well as the clinical course would seem to eliminate the possibility of any of the granulomas, and the exact limitation of the eruption to the areas supplied by the sensory divisions would rule out the diagnosis of a drug eruption such as is sometimes produced by phenolphthalein. The condition did not subside, leaving a residual pigmentation as is characteristic of phenolphthalein dermatitis.

The patient had had attacks of urticaria and mild attacks of flexoral eczema, which antedated the operation for trigeminal neuralgia. Lack of cooperation prevented our complete investigation of this phase of her condition, but the nature of the lesion and its limitation made it seem unlikely that the dermatitis was the manifestation of an allergic state.

A biopsy was not obtained. This request was not pressed because the patient was somewhat vindictive and refused to have any more operative procedures.

The patient threatened to file a suit for malpractice on account of the development of the dermatitis following the operation on the trigeminal nerve. This threat was not carried out, but it does suggest the possibility that such cases in addition to their unusual

clinical interest, might have some medicolegal significance. The reporting of such instances, and the more general recognition that such phenomena may appear following nerve destruction or injury, places the medical profession in a position to defend itself in such a circumstance.

RENAL RICKETS

REPORT OF CASE

ARTHUR R. ELLIOTT, MD
CHICAGO

L. M. S., a girl, aged 11 years, came under observation in November, 1917, for frequent urination and retarded growth. The birth of the patient was uncomplicated but the first year of life was rendered difficult by malnutrition, so that her body weight remained nearly stationary. At the age of 4, she began to have severe pains in the bladder and urinary cultures showed a colon bacillum. At the age of 10, she had an acute pyelonephritis, following which the urine remained persistently cloudy. She made no complaint of any special pain. She had never weighed more than 50 pounds (23 Kg.) and had grown slowly. She got up a number of times at night to urinate. She played with other children and apparently was of normal intelligence for her age.

Distention of ureters

Previous illnesses in the patient's experience, excluding what has been mentioned, were measles at 8 months of age, whooping cough at 11 months, double lobar pneumonia at the age of 8 years, and a single lobar pneumonia at the age of 10.

The family history was without significance.

The urine was cloudy with pus but not offensive. The blood pressure was 100 systolic, 70 diastolic. She was hospitalized

for urologic diagnosis. A cystoscopy under ether anesthesia, Nov. 9, 1917, showed an extreme cystitis of the bladder mucosa, with many folds and much vessel engorgement. Great difficulty was experienced in catheterizing the ureters because of the folds in the mucosa. Both ureteral openings were enlarged and crater-like. They seemed large enough to permit the passage of the tip of the little finger. The bladder and the ureters were injected with thorium showing the ureters to be greatly distended, as observable in the roentgenogram. All urine yielded *Bacillus coli-communis* in pure cultures. Examination of catheterized ureteral urine showed much pus and bacteria in both specimens. The roentgenograms revealed no stone shadows. The bladder was large, the ureters both dilated.

The patient was kept under observation for two years. The urine at all times contained much pus and bacteria. The blood count showed little departure from the average normal. At no time during the progress of the case to its termination was there noted any significant degree of anemia. The first blood count made in 1917 revealed red cells, 4,100,000, leukocytes, 5,400, hemoglobin, 80 per cent. The last count, made on July 5, 1930, revealed red cells, 4,560,000, leukocytes, 9,750, hemoglobin, 80 per cent. The child's physical development was markedly retarded. Her mental development was slow but along normal lines. The catamenia commenced late, were irregular for several years, and then became regular and painless. Breast development and axillary and pubic hair were normal. Her hair and teeth were unusually good. There was

never any sign of dental decay. Knock-knee was first observed at the age of 15. Its development was slow.

In April, 1928, at the age of 22, the patient was again hospitalized. No physical examination had been made by the reporter since 1918, ten years previous. Physical examination on the second admission to the hospital showed a very marked genu valgum causing so much interference that the patient had great difficulty in walking. Her weight was 72 pounds (33 Kg.) and her height 4 feet 4 inches (132 cm.). Roentgen examination of the right knee, elbow, and wrist gave definite evidence of epiphysitis involving the distal epiphysis of the right ulna and radius. There was a good deal of bone absorption, and the diaphyses were fuzzy. There was no evidence of pathologic involvement of the epiphyses of the bones of the right elbow. There was definite pathologic involvement of the epiphyses of the bones of the right knee. The epiphyseal lines were widened, irregular, hazy and rarefied. There seemed to be a widening of the distal third of the diaphysis of the right femur, which might have been due to bone absorption and to the weight bearing of the bone. The same was true of the proximal third of the diaphysis of the right tibia.

Laboratory Data

Date	Urea Nitrogen	Non protein Nitrogen	Uric Acid	Creatinine	Alkali Reserve, Cc	Blood Calcium	Cal Cholesterol	Blood Sugar	Phenol sulphonphthalein Kidney Function Test

11/10/28				5					
3/14/29		59		9.2					
6/21/29		130		6					
7/5/30		88.5		7.6		4.8	250		

The rachitic stigmas consisted of genu valgum, Harrison's groove, and slight changes about the wrist. The patient was found to have a mitral stenosis, well compensated. The urine was cloudy, containing a large number of colon bacilli, and gave forth the characteristic odor of a colon bacilluria.

The phenolsulphonphthalein kidney function test showed an output of 10 per cent in two hours.

The blood yielded urea, 59 mg., nonprotein nitrogen 138 mg., uric acid, 6.5 mg., creatinine, 5 mg.

The patient was very urgent in her request to have some surgical treatment of the knee condition but on the result of the examination this was judged to be clearly impossible. The chemical examination of the blood until the date of her death, which was from uremia in October, 1930, at the age of 24, is shown in the accompanying table.

COMMENT

In the records of this case is revealed the existence of chronic urinary infection, covering almost the entire period of the patient's twenty-four years of life. The effects of this long-standing colon bacillus infection on the bladder and urinary passages was to produce a chronic cystitis, double chronic ureteritis and pyelitis, with great dilatation of those cavities and atrophy of the renal parenchyma, constituting double hydronephrosis with secondary renal sclerosis.

A singular circumstance was that despite the high nitrogen concentration in the blood during the last two years of the patient's life, she had no elevation of blood pressure. At no time did it exceed 120 systolic, 80 diastolic. There was no retinitis or other change in the fundus, very little demonstrable arterial fibrosis and no uremic manifestations occurred until shortly before death.

This case constitutes a typical instance of what has been variously called "renal dwarfism," "renal rickets" and "renal infantilism." This last designation is misleading because cases do not all present the double con-

dition of rickets and sexual infantilism, as is illustrated by the foregoing history

The condition has been known since 1883, when it was first referred to by Lucas, who reported several cases of late rickets associated with albuminuria and stated that he considered the association significant. It has been a well defined clinical entity since 1911, when Fletcher demonstrated the etiologic connection between chronic kidney disease and the bone deformities present. The dwarfism and infantilism that accompany nephrosclerosis in children are not fully understood, but it is surmised that they represent the effects of the nephritis on the metabolic processes of the young growing organism. A moderately careful review of the literature reveals a total of eighty-four cases, only a small minority of these cases being reported in the American medical literature, not more than a dozen in all. Doubtless the reason for this is the lack of awareness on the part of the American medical profession regarding this condition, which has been studied much more intimately abroad, especially in England, the majority of the reported cases being found in English literature. An excellent review and critical analysis of the literature is that of A. Graeme Mitchell.¹

Many of the recorded cases are instances of nephrosclerosis (chronic interstitial nephritis) without obvious urinary infection. A survey of the reports available yields a total of ten cases in which pyuria and dilatation of the urinary passages resulting from chronic infection existed, the urinary infection having evidently led to destructive changes in the kidneys with overgrowth of interstitial tissue. Such chronic infection may develop in the absence of demonstrable obstruction of the urinary tract as well as when it is present.

In Mitchell's collected cases, special mention is made of "genu valgum" in thirty-three instances. This is the most prominent manifestation of rickets present. The average age when genu valgum develops is given as 9 years. The average age of onset of symptoms of thirty patients with renal rickets in which the age is given was 5 years and 2 months. The condition may be present from infancy as the result of congenital cystic kidney. Striking variation from chronic nephritis of similar degree in adult life consists in the absence of elevated blood pressure. An elevated blood pressure is rarely encountered in the literature of this disease in children. The highest blood pressure noted in the case here reported was 120 systolic, 80 diastolic, despite the high grade of azotemia that existed. In twenty-six of Mitchell's collected cases a high grade of nitrogen concentration was found often in extreme degree reaching in the terminal stages to 300 mg or more. The highest concentration appeared to be in infective kidney conditions such as double hydronephrosis.

Necropsy reports are relatively few but when reported the kidneys have shown a typical histologic picture of interstitial nephritis, varying in degree with the size of the kidney.

Mitchell propounds the theory that the kidneys in this disease fail to excrete the waste endogenous phosphorus from the body and that such waste is excreted through the intestinal mucosa instead of from the kidneys, this concentration of phosphorus in the bowel contents may interfere with the absorption of calcium from the food, through the formation of insoluble calcium phosphate thereby leading to rickets from calcium starvation. The value of this hypothesis has yet to be appraised.

SUMMARY

There exists a form of rickets developing in childhood in association with, and apparently as a result of, chronic nephritis. Other causes of persistent renal insufficiency, such as congenital cystic kidney and double hydronephrosis, may effect the same result. Bodily development is markedly retarded and, when the patient survives beyond the age of puberty, sexual infantilism may exist. Chemical studies of the blood reveal an increasing azotemia coinciding with the increasing excretory inadequacy of the kidney. Strangely enough, the blood pressure is not elevated until perhaps just before death. With the high concentration of blood nitrogen, there may be manifestations of uremia. Death usually results from the kidney insufficiency. Roentgen studies of the bony structures disclose the typical appearances of rickets. Genu valgum is the outstanding manifestation of the pathologic bone condition and may be the first symptom to call attention to the underlying kidney condition.

COD LIVER OIL CONCENTRATE (CONCENTRATED VITAMINS A AND D)

INEFFECTIVENESS OF LARGE DOSES IN THE PROPHYLAXIS OF OTITIS MEDIA COMPLICATING SCARLET FEVER

W. D. SUTLIFF, M.D.

EDWIN H. PLACE, M.D.

AND

SAMUEL H. SEGOOL, M.D.

BOSTON

The frequency with which localized purulent infections appear on the mucous membranes of animals and of men deprived of vitamin A has led to the view that an adequate supply of this vitamin may be essential for the maintenance of resistance to infection. It is logical to inquire whether certain purulent complications of the acute infectious diseases of childhood may not be prevented by supplying large amounts of vitamin A. An approach to an answer for this question has been made in the work to be reported. The otitis media following scarlet fever was chosen as the most suitable purulent infection for observation because of the following reasons. It develops at a site commonly infected in vitamin A deficient animals, it is relatively simple to diagnose, it occurs with considerable frequency and regularity, and it usually appears in the second, third and even fourth week of the disease, thus giving an opportunity for adequate prophylactic treatment. In the present study the nonsaponifiable fraction of cod liver oil containing vitamins A and D in concentrated form was given to a series of patients with scarlet fever, and the incidence of otitis media observed and compared with the incidence in a control series.

Observation of animals and man by physiologists, clinicians and pathologists has led to the impression that vitamin A deficiency is associated with lowered resistance to infection. Infections have been noted accompanying states of general malnutrition as well as various specific vitamin deficiencies but no such marked correlation has been reported or rationally developed as

¹ Mitchell, A. C. Nephrosclerosis (Chronic Interstitial Nephritis) in Child. *Chil. Abn. Dis.* 40: 101 (June) 1945 (Abn.) 19.

that to be described later for vitamin A and infections. The relationship of vitamin D deficiency, for example, to the development of infections has not seemed comparable with the relationship of vitamin A, and while both these vitamins were present in the cod liver oil concentrate used prophylactically in this study, attention has been directed almost entirely to the latter.

Daniels and Armstrong,¹ Green and Mellanby,² Turner and Loew,³ and Sherman and Burtis⁴ have noted a high incidence of infections in animals fed vitamin A deficient diets. These authors list sinusitis, middle ear disease, bronchitis, pneumonia and pyelitis as occurring much more frequently in young rats fed vitamin A deficient diets than in control animals. The organisms isolated from well localized abscesses in the sinus lesions accompanying vitamin A deficiency in the rat are not of one variety but represent the natural flora of the cavities in which the abscesses developed.⁵ It is unlikely, therefore, that the mechanism of the development of the infections depends on the creation of conditions favorable to the development of any particular organism, but probably on a change in the natural protective forces which are effective against the normal flora. Other animal species react differently to vitamin A deprivation. Thus, guinea-pigs⁶ and monkeys⁷ succumb to colitis and do not show xerophthalmia or purulent infections. A uniform basis for the variable site of the infections complicating vitamin A deficiency in different species of experimental animals is obtained from the microscopic study of sites most favored by infection. Mori⁸ and Wolbach and Howe⁹ in the rat, Wolbach and Howe⁶ in the guinea-pig, Seifried¹⁰ in the chicken, and Tilden and Miller⁷ in the monkey have observed the development of keratinizing epithelium on the mucous surfaces on which infections arise.

Infections, including otitis media, have been described in children with xerophthalmia by Bloch,¹¹ in the skin and mucous membranes of adults by Frazier and Hu,¹² and microscopic changes in the epithelium of the mucous membrane have been recorded in a child by Wilson and DuBois.¹³ The patients observed by these authors probably suffered from diets deficient in more than one necessary factor. Their conclusions are to be

accepted with a certain reserve, but the similarity of the disease symptoms with those of vitamin A deficiency in animals, the lack of vitamin A in their diets, and their response to the administration of foods rich in vitamin A serve to indicate that vitamin A deficiency is the most likely factor and that the information gained by experimentation can be applied to conditions in man.

In summary, a lesion of the epithelial structures follows vitamin A deficiency in animals and man, the site of which differs in different species. These changes are followed by inflammation, often purulent, in which organisms, normally present, are the chief bacterial agents. The therapy or prevention of such conditions by means of the administration of vitamin A is suggested.

It has been established that the correction of at least some of the pathologic changes in experimental vitamin A deficiency is fairly rapid and complete when this dietary factor is supplied in proper amounts before marked infection appears.¹⁴ Bloch,¹⁵ Frazier and Hu,¹² and Pillat¹⁶ have reported success even in the therapy of well developed disease in man. After abscesses or severe diarrheas have appeared, however, in animals, the administration of vitamin A, while sometimes apparently beneficial, does not often result in complete or rapid cure. On the other hand, the maintenance of an adequate supply of vitamin A is an effective prophylactic measure. One might expect that similar relationships would be present in the use of vitamin A therapy in man, namely, that well developed infections would be resistant to therapy but that such infections might be prevented or minimized by maintaining an adequate vitamin A intake.

Various applications of anti-infective vitamin therapy in man have been reported. Dean¹⁷ has treated chronic infections in the paranasal sinuses of children without success. Wright, Frosst, Puchel and Lawrence¹⁸ have reported the careful study, through a period of winter months, of sixty infants less than 2 years of age in a foundlings' home. The twenty infants who were given extra amounts of cod liver oil concentrate showed an incidence of respiratory infections equal to that in the forty control infants. Barenberg and Lewis,¹⁹ whose work has been discussed at length by Hess,²⁰ likewise found no difference in the incidence of respiratory infection between groups of hospitalized infants receiving different amounts of vitamin A in their diets. In contrast to the discouraging reports of others, Green, Pindar, Davis and Mellanby²¹ were encouraged by finding that, among 275 women treated for one month before term with large doses of vitamin A, the morbidity from puerperal fever was 11 per cent, as compared to 47 per cent in an equal number of controls.

The prophylaxis of the otitis media of scarlet fever offers a test of the anti-infective properties of large

doses of cod liver oil concentrate, which has a number of advantages over the tests done by others. There is a possibility that dietary deficiencies, of either marked or relative degree to the needs of growing children with infections, are present in the subjects. Otitis media is a uniform condition due, usually, to a hemolytic streptococcus and developing with a uniform frequency, which may be quite accurately determined and which is great enough to make statistical analysis reliable. Any influence of the high vitamin A dosage on the incidence of otitis media would lead to significant conclusions in regard to the etiology and treatment of the otitis media of scarlet fever and, possibly, in regard to otitis media or sinus infection in general.

SUBJECTS, MATERIALS, METHODS

All the patients with scarlet fever admitted to the South Department of the Boston City Hospital during the five months from December, 1930, to April, 1931, inclusive, numbering 509, were included in the treated series. These patients were not suffering from obvious malnutrition, xerophthalmia or hemeralopia, and, while in the hospital, received a diet containing amounts of the various vitamins which normally are considered adequate. They represent a group in which borderline, clinically unrecognizable vitamin A deficiency states, such as those described by Thatcher and Sure,²² might occur. Their age⁴ and the bacterial infections from which they suffered²¹ might tend to make their vitamin A requirements abnormally large.

The incidence of otitis media was studied from the records of 343 scarlet fever patients admitted during the five months from December, 1928, to April, 1929, inclusive, as a control. The general treatment was quite similar in the series of the two different periods. Scarlet fever antitoxin was used but had no effect on the incidence of otitis media, which was 12.6 per cent, or 24 cases, among 189 in which antitoxic serum was given, and 12.3 per cent, or 24 cases, among 194 in which antitoxic serum was not given.

The criteria for otitis media were the presence of redness and bulging of the tympanic membrane, obscuring of the malleus and loss of the light reflex. All but a few of such tympanic membranes were incised or spontaneously ruptured. The onset of the otitis media was taken to be the time of the first complaint of pain or the first observation of changes in the tympanic membrane. Only patients who were found on admission to have normal ear drums were included in the analysis. The inclusion of patients admitted to the hospital with a preexisting otitis media might alter the expected incidence which is quite constant from year to year when only cases developing under the constant conditions of a hospital are considered.²³

The cod liver oil concentrate²⁴ was a nonsaponifiable portion of the oil, suspended to 25 per cent by weight in a cod liver oil menstruum to prevent deterioration, and furnished in bulk and in 10 minim capsules. The potency of this preparation in terms of both vitamins A and D was found by the manufacturer to be about twenty times that of a good preparation of cod liver oil. The vitamin D units were 3,000 per cubic centimeter. The potency of the preparation in terms of vitamin A is

not so easily stated on account of the lack of a generally accepted standard of measurement. An assay method was used by the manufacturer which included observation of and cure of xerophthalmia, in addition to weight loss, in the rat. In terms of the unit thus determined, by which a good specimen of cod liver oil (1,000 U S P units per cubic centimeter) contains 500 units per cubic centimeter, the concentrated material contained 10,000 units per cubic centimeter. Each 10 minim capsule contained approximately 2,000 of these vitamin units. A confirmation of the vitamin A potency of this cod liver oil preparation was obtained through the courtesy of Dr. C. C. Ungley and Dr. M. M. Suzman, who estimated the potency according to the Carr and Price²⁵ antimony trichloride method, reading the resulting reaction with the Rosenheim-Schuster²⁶ modification of the Lovibond tintometer, with calculations carried out according to the method of Moore.²⁷ A reading of 30,800 "blue" units per cubic centimeter was obtained, which is about twenty-five times the "blue" units found in a good sample of cod liver oil. One thousand minims of the concentrate was approximately the equivalent in vitamin A potency of 400 cc of cod liver oil (1,000 U S P units per cubic centimeter). Although there is no generally accepted method of determining vitamin A potency, the comparisons mentioned are sufficient assurance that a highly potent preparation was employed.

A daily dose of 100 minims was thought adequate to provide the patients with a sufficiently large amount of vitamin A during the time preceding the expected development of otitis media. The 100 minims was administered in five capsules morning and evening, or as 50 minims morning and evening, in orange juice, for the first ten days in the hospital. A special record was kept of each successfully administered dose by the nursing staff. Owing to the fact that the initial supply was entirely in 10 minim capsules, which were taken by the patients only following careful instruction, a substantial number of patients did not receive the total dose. Fifty-one per cent, or 261 patients, received from 900 to 1,200 minims in ten days, 28 per cent, or 141 patients, received from 500 to 900 minims in ten days, 8 per cent, or 41 patients, received less than 500 minims, and 13 per cent, or 66 patients, received none. Since the incidence of otitis media was quite similar in the group of patients receiving the standard dose to that in the group of patients receiving less, no subdivision of the treated group of patients on the basis of varying dosage is made in the accompanying tables.

RESULTS

The incidence of otitis media found in the test and control periods was quite similar to that reported by others (Gunn and Griffith,²⁸ Dahlberg and Sydow,²⁹ Woody,³⁰ Ludy, Hunt and Cogswell,³¹ Gardner³² and Harries and Gillespie³³). There was no difference in

Total		39	11.3		48	9.4

otitis media was quite similar in comparable age groups in the treated and control series

Owing to the administration of the cod liver oil only during the first ten days the patients were in the hospital, it was conceivable that the effect on the incidence of otitis media might bear some relationship in time to the therapy The arrangement of the cases of otitis media for the two different periods, according to the

length of time elapsing in the hospital before the onset of otitis media, shows fewer cases in the first week of the hospital stay in the patients treated with vitamin A but no other marked differences It would seem that this variation probably had no relation to the administration of the cod liver oil concentrate

SUMMARY

The total incidence of otitis media in 343 cases of scarlet fever during five months was 11.3 per cent, a figure corresponding closely to that recorded by others The total incidence of this complication in 509 similar cases observed during five months at the same time of year two years later, most of which were treated for ten days after admission to the hospital with a total of 400,000 U S P units of vitamin A contained in a concentrated preparation of cod liver oil, was 9.4 per cent

The use of cod liver oil concentrate in such dosage had apparently no effect on the liability of the scarlet fever patients to develop otitis media

A PROTOZOAL SURVEY OF ONE THOUSAND PRISONERS

WITH CLINICAL DATA ON NINETY-TWO CASES OF AMEBIASIS

H G JOHNSTONE, MA
N A DAVID, MD
AND
A C REED, MD
SAN FRANCISCO

It has been suggested in several recent articles¹ that the incidence of amebic (*Endamoeba histolytica*) infestation among the people of the United States may be higher than is generally believed While no statistics are available dealing specifically with the degree of amebic (*E. histolytica*) infestation of "healthy" normal adults in different parts of this country, other data may be used, by comparison, to support this belief For instance, recent statistics, such as those presented in the studies referred to, show for individuals examined an average incidence of about 12 to 15 per cent infestation with *E. histolytica* It must be noted that this rather high figure is obtained from studies chiefly in the so-called protozoal endemic areas (California the Mexican border and the Gulf states) and moreover on sick people seeking treatment either from private physicians or from hospitals and clinics It is assumed that a high incidence of infestation among the sick naturally presupposes a similar high figure for the general population Certain workers² have estimated that the probable incidence for the whole country is as high as 10 per cent and even higher in areas in which amebic dysentery is endemic

There is reason to believe that there has been an actual increase of amebic infestation in this country in

the last decade. Better laboratory methods as well as the growing realization by the medical profession of the importance of routine stool examinations have led to the more frequent diagnosis of amebiasis. It seems that these factors do not completely account for the increase in the number of cases reported in recent years. This is not surprising when one considers the epidemiologic conditions that have favored the spread of amebas since the time this country was first settled. We need only mention them here.

SPREAD OF PROTOZOA

There has been continual immigration into this country of ameba-infested peoples, beginning with the importation of Negro slaves from Africa. During the latter half of the nineteenth century great numbers of Chinese coolies and Japanese farmers came to the Pacific Coast, and Hindu laborers were brought in to work on the railroads. In more recent years there has been a great influx of Filipinos and Mexicans. These peoples through their unhygienic habits have served to spread the infestation wherever they have settled.

It must also be considered that large numbers of our own people migrate to endemic areas and return home infested. Our attention was first called to this when thousands of soldiers sent to the Philippines contracted amebic dysentery. Many of the Panama Canal workers returned to this country infested. The last great mass infestation of our people occurred in France during the World War, when certain divisions of our soldiers took over sectors formerly held by ameba-infected French-African troops. Kofoid's³ studies made on returning soldiers showing a high incidence of amebic (*E. histolytica*) infestation support this statement.

Another important factor favoring the spread of protozoal infestation has been due to the food fads of recent years. The public in its demand for more vitamins and roughage in the diet has greatly increased its consumption of fruits and raw vegetables. These products sometimes come from parts of the country that are highly endemic for amebiasis. Contamination is easy. Lack of cooking removes one factor of safety. Lack of personal hygiene and cleanliness makes still easier the transfer of cysts. Infestation with amebas invariably means preceding ingestion of fecal material. Amebiasis is essentially endemic and probably the most important single method of spread is by infested food handlers. When food handlers are of a race or from a place in which amebiasis is abundant, the chances for spread are enormously increased. All these various factors have no doubt played a large part in the spread of amebiasis in this country.

In view of the fact that statistics are meager in regard to the true incidence of amebic infestation, it seemed to us of value to carry out a protozoal survey of supposedly healthy adults representing a cross section of the general population. We were afforded such an opportunity through the kindness of Dr. L. L. Stanley, medical director of the California State Penitentiary at San Quentin, who permitted us to carry out a systematic protozoal survey on the prison inmates. We hoped by this work to accomplish two things: to establish the incidence of protozoal infestation of unselected cases of presumably healthy male adults in California and by summary and compilation of clinical data, to investigate the relationship between the infestation and

residential history on the one hand for cases of amebiasis, and the clinical symptoms and the infestation on the other. In addition, we wished to treat the men found harboring *E. histolytica* with two new amebicidal drugs, Carbarsone and Vioform,⁴ developed by Leake and his co-workers.⁵

SOURCE OF PATIENTS

Men from all over the state of California are sent to San Quentin Penitentiary. More than 5,000 men are housed here continuously,⁶ with about 1,500 men being discharged or paroled and a like number admitted annually. The average age for these men is between 20 and 30 years.

It was planned to limit the survey to entering men and to examine 1,000 of them. But soon after treatment was begun on the men found harboring *E. histolytica*, the problem arose as to the possibility of their reinfestation by food handlers within the prison. In order to avoid this danger it was decided to include in our protozoal survey the 250 inmates on the mess force.

LABORATORY METHODS

The men reported each morning after breakfast for three successive days to a special laboratory, where stool specimens were obtained. Thin fecal smears were made at once from these specimens by a trained technician. Numbered glass slides and horsehair paste brushes were used for this purpose and the wet smears were immersed in Schaudinn's fixing fluid.⁷ After twenty-four hours' fixation, the slides were transferred to iodine-alcohol solution and then to 70 per cent alcohol, in which they were mailed to the laboratory to be subsequently stained and examined.

Staining and examination of the slides were done at the laboratory of the Pacific Institute of Tropical Medicine in San Francisco. The iron-hematoxylin method was used. Slides found positive for *E. histolytica* were filed for permanent record. It was noticed that patients with *E. histolytica* infestation usually had concurrent infestations with one or more other protozoa.

RESULTS OF PROTOZOAL SURVEY

In this study exactly 1,000 men were examined. With the exception of the 250 food handlers, all were new entrants. Only three men were examined because of symptoms, and they each proved positive for *E. histolytica* and are included in the ninety-two cases reported as positive. Table 1 shows the incidence of protozoan infection for the men examined at San Quentin as compared with other hospital surveys and with the report of the California State Board of Health.⁸ It is interesting to note that the incidence of infestation with *E. histolytica* for the group we studied nearly approaches that found by Kessel¹ for hospital entries at Los Angeles in 1929. Excluding the three cases presenting symptoms from our ninety-two cases of amebiasis, the incidence for "healthy" adults is 8.9 per cent, or about 1 per cent less than Kessel's

4 The first forty seven cases found have been treated with Carbarsone and will be considered in a separate report. Vioform (V. V. R.) has been used to treat the remainder of the cases. Its clinical use will also be the subject of a special report.

figure (The term "healthy" is used because these men appeared well and had no complaints severe enough to warrant hospitalization. As Craig⁹ says, strictly speaking, there is no such thing as a "healthy" carrier.)

Interesting also is the fact that eighteen cases (7.2 per cent) of *E. histolytica* infestation were found among the 250 men on the prison mess force. It will be noted that some workers distinguish between *E. coli*

and *Councilmania lacturi* and that the incidences given for these two organisms vary greatly. Kessel attributes this variance to the personal factor entering into the differentiation between *E. coli* and *C. lacturi* and to the fact that there are many cases of mixed infestation which show considerable variation from day to day in the same patient. We have simply classified both forms as *E. coli*. Our incidence of 20.2 per cent *E. coli* is nearly the same as Kofoed's finding of 21.1 per cent for both *E. coli* and *C. lacturi* together, and slightly higher than Kessel's figure of 18.6 per cent for the two organisms. Our figures for three of the other commonly found protozoa are the highest of those in the

TABLE 2—Concurrent Protozoan Infestations in Ninety-Two *E. histolytica* Cases

Protozoa	Number of Cases	Per Cent
<i>Endamoeba coli</i>	34	37.0

<i>Iodamoeba butschlii</i>	20	31.5
<i>Giardia lamblia</i>	12	13.0
<i>Chilomastix mesnili</i>	3	3.2
<i>Trichomonas hominis</i>	1	0.9

table, an incidence of 26.3 per cent for *E. nana*, 12.5 per cent for *Iodamoeba* and 7.0 per cent for *Giardia*. *Chilomastix* was noted in only 2.3 cases of the 1,000 examined, while only 0.2 cases of *Trichomonas* infestation are recorded. We have no explanation to offer for these low figures.

Table 2 shows the incidence of concomitant protozoa in the ninety-two persons in whom *E. histolytica* were found. It is presented here merely to show that infestation with *E. histolytica* is often not a single protozoal infestation.

⁹ Craig (footnote 1, fourth reference).

CLINICAL SURVEY

Each new arrival at San Quentin Penitentiary has a thorough physical examination and a complete medical history taken by one of Dr. Stanley's staff. Routine Wassermann tests are done in all cases. The clinical records of the ninety-two cases positive for *E. histolytica* were used in compiling the data presented here. An additional history was taken on these men to determine whether they had at any time suffered from symptoms referable to the gastro-intestinal tract or had had any other conditions that might be considered due to amebic infestation. A complete residential record was also obtained from each man.

The average age for the group was 28.5 years. Of nationalities represented, there were sixty-four Americans, four American born Negroes, eleven Mexicans, four Italians, three of whom were born in this country, two Filipinos, and seven others of foreign parentage, five of whom were born here. A total of seventy-six were born in the United States. The number of men giving occupations concerned with the handling of food is higher than would otherwise be expected, as 250 of the men were from the mess force. There were ten cooks, seven bakers, four waiters, six dairymen and three butchers. Various other trades were represented by one or two men in each group, and seventeen men were classed as laborers.

RESIDENTIAL HISTORY

It is interesting to observe that seventy-eight of the ninety-two men, or 84 per cent, gave a history either of having at one time lived in areas in which amebiasis is known to be endemic or of having visited these localities for short periods. Twenty-three men gave a history of tropical residence other than Mexico. Six had been for some time in the Orient, five in Panama, four in the Philippines, five in South America or Cuba and three in Hawaii. Some of these men had been in Mexico as well and so are included in the total of eighteen men having lived in that country, while eleven of the eighteen were native born Mexicans. A total of thirty-six had had tropical residence, while six had visited Tra Juana. Fifty-six men had resided in Los Angeles or southern California and four others had stayed in these places for short periods. In addition, thirty-seven of these fifty-six men had also lived along the Mexican border or had been in Mexico or other tropical countries. The others, numbering nineteen men, had resided only in Los Angeles with the exception of two, who had been in France during the war. A total of eighteen had at one time lived along the Mexican border, some of whom claimed tropical residence as well, while thirteen had also lived in southern California, and so are included in the fifty-six men mentioned.

The small number of fourteen men gave no history of tropical residence or of having ever lived in southern California or along the Mexican border. However, nine of these men had lived for most of their lives in the Sacramento or San Joaquin valleys of California, where amebiasis is endemic. From the varied residential histories given, it may be observed that many of the men resided in several places endemic for amebiasis and so may have been exposed to infestation with *E. histolytica* in any one of these localities.

CLINICAL SYMPTOMS

We believe that the thousand men we have examined are fairly representative of the general population as far as matters of health are concerned. However, the

use of the term "healthy" applied to the subjects with amebiasis immediately raises the question of whether or not one can consider carriers of *E. histolytica* as healthy even though they may have no complaints at the time of examination. It is our belief that the presence of *E. histolytica* in the colon is sufficient to excite symptoms which may be vague or severe, depending on the quantity of pathologic changes. The absence of important symptomatology in this survey can be attributed to the fact that the men found harboring *E. histolytica* were mostly young and of a type paying little attention to mild symptoms. We found that of the thirty-nine men who had no gastro-intestinal complaints, twenty-seven were under thirty years of age. There was one case in which no special history was taken.

Of the thirty-nine men admitting no complaints referable to the gastro-intestinal tract, there were sixteen who had palpable sigmoides, which is of small clinical significance. A majority of the men, fifty-two, had experienced notable gastro-intestinal upsets. Of these must be mentioned again the three men examined because of the presence of dysentery, pains and gas, and another who had recently had a severe attack of dysentery. Twelve others had suffered from attacks of diarrhea, some of which may have been true dysentery although the patients do not remember having passed blood in their stools. Constipation was complained of in twenty-three cases, in several of which attacks of diarrhea had also occurred and so are included in the twelve cases given. There were twenty-eight patients who complained of indigestion, of whom twelve had abdominal pain as the only symptom and three others who had noticed only the belching of gas or a "bloated feeling." Nine men had both pain and gas, while an additional four had suffered from nausea and dizzy spells following meals. Many of these twenty-eight men had other complaints as well, such as constipation or diarrhea. The sigmoid was found palpable in twenty-two of the fifty-two men who had gastro-intestinal symptoms. Of miscellaneous other associated intestinal disturbances or diagnoses, four men had hemorrhoids, three had been operated on for rectal diseases, six for appendicitis and one for stomach ulcer. There was one case of amebic abscess of the liver. The duration of these gastro-intestinal symptoms, when known, averaged four and one-half years.

ASSOCIATED DIAGNOSES

We have included other interesting observations on the ninety-two men afflicted with amebiasis, not because they have any direct relation to amebic infestation but rather because they indicate the type of men we have examined. There were twenty-eight cases of gonorrhea, an incidence of 30 per cent. One may say that this as well as the varied residential history indicates the careless manner of living of these men and suggests a similar carelessness in food habits. There were ten who had had smallpox, which they had probably contracted because of their residence in tropical areas, where this disease as well as amebiasis is common. Six had had typhoid. However, it is noteworthy that only two gave a history of having had malaria, in spite of the high percentage having lived in tropical areas.

Only five men gave a history of syphilis, of whom four were positive on entry as shown by the Wassermann test. Of other diseases noted tuberculosis is the only one worthy of mention as it was found or suspected in seven cases. There were twelve men who complained of rheumatism.

SUMMARY

1 In a protozoal survey of 1,000 inmates at San Quentin Prison, infestation with *E. histolytica* was found in 92 per cent.

2 Seventy-eight of the ninety-two men with *E. histolytica* infestation lived in or had visited areas in which it is well known that amebiasis is endemic, and thirty-six of these had lived in tropical regions at one time.

3 Fifty-two men had experienced notable gastro-intestinal upsets, twenty-eight having complained of indigestion, sixteen of diarrhea or dysentery, and twenty-three were bothered with constipation when examined.

4 Thirty-nine men stated that they did not have gastro-intestinal complaints. Of these, twenty-seven were under 30 years of age and in most cases had only recently been to endemic areas.

EFFECT OF HYPERTONIC DEXTROSE SOLUTIONS ON INTRACRANIAL PRESSURE

IN ACUTE CRANIAL INJURIES

HARRY JACKSON, M.D.

WITH THE ASSISTANCE OF

TOSHIO KUTSUNAI, M.D.

L. O. LEADER, M.D.

AND

L. D. JOSEPH, M.D.

CHICAGO

It has been a matter of general knowledge for many years that the most important finding in acute traumatic injury to the brain is increased intracranial pressure. This is caused by three factors: swelling of the brain due to hemorrhage, congestion and edema, increase in the amount of cerebrospinal fluid in the ventricles and cisterns, and increase in blood pressure. In a general way, the reaction of these three factors on one another may be explained as follows. The brain, encased and protected within a rigid bone box and covered by a thick, practically nondistensible dura mater, has little excess space to accommodate the hemorrhage, congestion and edema that accompany injury. As the cortex becomes swollen, it presses tightly against the dura and cranium and restricts the outflow of cerebrospinal fluid and blood through the cranial sinuses. This backpressure on the cerebrospinal fluid, whose production is increased by the active hyperemia of the choroid plexuses, distends the ventricles and aggravates the pressure already present on the cortex. Further accumulation of cerebrospinal fluid and blood in the basal cisterns irritates the vital centers in the medulla, and the pulse is slowed and blood pressure increased. These three factors continue to react on one another, setting up a vicious spiral that increases the intracranial pressure and eventually brings about the death of the patient unless it is adequately relieved.

Attempts have been made, from time to time, to break up this vicious spiral by attacking one or more of these three factors. Venesection was practiced to reduce blood pressure. This, of course, was of little help. Later, the operative procedure of subtemporal decom-

From the Department of Surgery, Cook County Hospital, Read before the Chicago Surgical Society, Oct. 7, 1932. Owing to lack of space this article is abbreviated here by the omission of a table summarizing the clinical observations in twenty cases. The complete article appears in the authors' reprints.

pression was widely used to relieve pressure on the cortex and allow for possible drainage of cerebrospinal fluid. This was inadequate, as I showed about ten years ago in a paper presented before the Chicago Surgical Society. At that time, believing that reduction of cerebrospinal fluid and blood content was the best means of relieving all the intracranial pressure symptoms, I advocated the repeated removal of this fluid by lumbar drainage, and this method has been widely used with very good results. More recently the intravenous injection of hypertonic solutions has been advocated to reduce brain volume and cerebrospinal fluid content.

The experiments of Weed and McKibben¹ in 1919 on normal cats showed that intravenous injections of hypertonic salt solutions caused a shrinkage of the brain as well as a loss of water from all tissues and parenchymatous organs of the body. Clinicians soon utilized this knowledge to reduce brain volume in all states of increased intracranial pressure. Hypertonic solutions of sodium chloride were first used up to 20 and 30 per cent in strength, but the results in the injured human subject were not so successful as the experiments on normal animals indicated. Patients developed convulsive attacks, breathing became labored, and some patients went into a state of coma and died. It has since been shown that the brain cells gave up some of their fluid content for a brief period while the salt was still present in the blood stream, but later when the salt had passed from the blood vessels into the brain cells, which seemed to have an avidity for sodium chloride, fluid flowed back again into the cells and the swelling of the brain recurred to a greater extent than before.² Other solutions were then substituted for sodium chloride. Magnesium sulphate, with its power of attracting water into the intestinal tract, was given both by mouth and by enema, with seemingly good results. It has also been given intravenously in small doses. Later dextrose was used intravenously in from 25 to 50 per cent solution. From 100 to 200 cc of dextrose solution was injected into the veins of the forearm, and favorable clinical reports from its use in cranial injury were made by a number of clinicians.

Exact determinations of the amount of reduction in cerebrospinal fluid pressure were not made, but the method has nevertheless become quite popular and is in common use today.

In order to determine accurately the efficacy of this method in acute cranial injury in man, I have used it in many cases and herewith report my results in twenty clinical cases. In ten cases, 100 cc of 50 per cent solution was used and, in ten cases, 200 cc of 25 per cent solution. The solution was injected slowly during a period of from twenty-five to thirty minutes into the veins of the forearm. Patients were chosen with moderately severe states of increased intracranial pressure due to cranial injury. In order to make observations extending over several hours, patients were chosen who had recovered from shock and were fairly quiet or stuporous. Cases of depressed fracture and bleeding from the middle meningeal artery were ruled out. A spinal puncture was made in the second lumbar interspace, with the patient lying on his side, the head being on a level with the spine. With a mercury manometer, readings were taken of the spinal pressure without allowing more than a drop or two of spinal fluid to

escape, to determine presence of blood and a free tap. A record of the pulse, blood pressure and respiration was kept during the experiment. The spinal needle was left in place whenever possible, to record changes in spinal fluid pressure. In unruly patients, readings were taken by repeated punctures. These experiments have been carried on during the past four years. In seven cases, very accurate determinations were possible over the first two hours. In thirteen other cases, favorable observations were made over a period of from twenty-four to forty-eight hours. In all twenty cases, similar results were observed.

These results may be summarized as follows. In eleven cases there was an initial drop in pressure of from 1 to 4 mm of mercury during the first thirty minutes, then a gradual rise to a point above the initial pressure in two hours. In some cases this increase amounted to as much as 50 per cent of the original pressure. This was reduced to the initial pressure in twenty-four hours. In nine cases, however, the rise was immediate and continuous for two hours, with slight fluctuations, and gradually returned to the initial pressure in twenty-four hours. In about half the cases the blood pressure rose and the respiration became labored. This was more evident with the 50 per cent solution than when 25 per cent solution was used, but it occurred with both. Headache was relieved for a short time in some cases, but not to the degree of relief obtained when spinal fluid was withdrawn, as was done in several cases. Milles and Hurwitz³ obtained similar results in normal animals after two hours, showing an initial fall in pressure, followed by a secondary rise and toxicity. Ernst,⁴ in a lengthy study involving experiments on normal cats, shows curves in which there is an initial fall in pressure followed by a secondary rise after two hours, but he fails to comment on this phenomenon. Browder⁵ cites similar results in human cases.

How is one to explain these results? Is it possible that dextrose behaves similarly to sodium chloride? It is evident that the effect of hypertonic solutions injected intravenously differs in normal animals from that found in human cases of cerebral injury. The rise in pressure is more prompt in the human cases, occurring in from twenty to thirty minutes. In the animal experiment on uninjured brains, the pressure increases after two hours, as shown by Milles and Hurwitz.³ In animals whose brains have suffered trauma, the rise is immediate and prolonged. This has been proved by Hoff, in a series of experiments on animals whose brains have been injured by dropping a weight from a height on their heads. He finds an initial congestion of the cortical vessels and choroid plexus, with increased secretion of cerebrospinal fluid dilating the ventricles. The tissues in the neighborhood of the ventricles absorb the cerebrospinal fluid under pressure, producing a secondary compression of the cortical vessels and sinuses and preventing outflow of venous blood. If salt solution or dextrose is injected intravenously during this stage, some of it is held in the brain cells and causes a secondary swelling of the brain, aggravating the intracranial pressure. In the human being the increase in pressure is produced in the same way.

DIABETES MORTALITY—DROLET

DIABETES MORTALITY IN NEW YORK CITY DURING THE THIRTY-YEAR PERIOD 1901-1931

GODIAS J. DROLET

Statistician New York Tuberculosis and Health Association
NEW YORK

In 1901 there were 501 deaths from diabetes recorded in New York City, in 1931, nearly four times as many, namely, 1,921 deaths, even though insulin had been available for a decade.

True, during these thirty years, New York's population has materially increased, in fact, doubled from three and a half millions to seven millions. Secondly, in that metropolitan center is included an unusually large proportion of Jews, with their higher susceptibility to diabetes, who are estimated to total now nearly two millions, or almost 30 per cent of the entire city. Thirdly, there has also to be taken into consideration the fact that—with the decreasing birth rate, 24 per thousand in 1901 and only 16 in 1931 along with the more effective control of infectious diseases, especially among children, and of tuberculosis more prevalent among younger adults—the composition or

Chart 1—Diabetes deaths in the two sexes in New York City since 1910

age distribution of the population has been materially altered, or, as it is now being described, New York has 'aged' considerably. While the federal census of 1900 showed here in a million males 157,625 past the age of 45 the enumeration of 1930 brought out that the same group contained 211,077, among females, practically the same change in a given million, namely, a rise, during thirty years roughly, from 160,000 to 212,000 past middle adult life. Therefore, while the crude death rate from diabetes per hundred thousand of population had risen from 14.2 in 1901 to 27.1 in 1931, or nearly doubled, the standardized rate, taking into account growth, and adjusted for comparison on the basis of a similar age composition throughout the thirty-year period changed from 17.3 to 27.9, or truly rose by 58 per cent.

RISE AMONG WOMEN

The increase in diabetes mortality has not, however, been the same for the two sexes and, as noted elsewhere lately, should be said to be almost wholly confined to females. For instance the standardized death rate in the male sex in New York during the quinquennium

A review based on Reports Department of Health City of New York
1. Lee W. W. The Recent Mortality from Diabetes in the United States J. Prev. Med. 2: 6 (Nov.) 1929

VOLUME 100
NUMBER 10

From my results in the human subject with an acute brain injury, and from Hoff's experiments on dogs whose brains were traumatized, it is evident that the conditions are quite different from those in the normal animal, and any deductions made from experiments on normal animals must be carefully qualified. This picture is in accord with my observations published ten years ago,⁶ which were based on postmortem examinations while I was a pathologist to the Cook County Hospital during the years 1912 to 1918, and clinical and experimental work done between 1919 and 1922. I found at that time, in cases of cranial injury, a most marked accumulation of cerebrospinal fluid in the ventricles, causing them to distend and push the cerebral cortex out tightly against the dura, compressing the cortical vessels and sinuses. Furthermore, there was marked accumulation of fluid in the basal cisterns and about the medulla extending downward into the spinal canal. The edema of the brain was not marked in most cases, and was inhibited by the pressure put on it by the distention of the ventricles and cisterns. As the outlet to the cerebrospinal fluid was hindered by the pressure exerted on the cortex and sinuses by the distended ventricles, the increased pressure could be relieved only by withdrawal of cerebrospinal fluid and blood from below the tentorium cerebelli. Not only did emptying of the basal cisterns relieve all medullary symptoms of slow pulse, stertorous respiration, and increased blood pressure, but also emptying of the ventricles allowed the cortex to fall away from the dura and permitted normal functioning of the cortical vessels and sinuses to take place. This eventually resulted in relief of the congestion and edema of the brain, which gradually subsided in about seventy-two hours in moderately severe cases. The importance of keeping open the pathway of cerebrospinal fluid circulation and absorption through the cranial sinuses was stressed by me in a paper published in 1922.⁷

CONCLUSIONS

1 The use of hypertonic dextrose solutions in acute states of intracranial hypertension due to injury of the brain in man results in immediate increase of pressure in half of the cases, in slight temporary reduction of the pressure in half of the cases and in secondary increase in all the cases after from fifteen to thirty minutes. This is due to pressure on the return venous flow in the sinuses of the brain.

2 In normal animals used for experimental purposes, there is a primary fall in pressure because there is no hindrance to the circulation in the sinuses, the secondary rise in pressure is due to the absorption of dextrose by the brain cells and causes edema of the brain, but to a less extent than was found when sodium chloride was used.

COMMENT

Hypertonic dextrose solutions not only do not appreciably lower intracranial pressure as measured directly by the spinal manometer, but in many cases the pressure is actually increased. The use of these solutions leads to a false sense of security in the treatment of acute cranial injuries, allowing prolonged pressure on the cortex of the brain and leading to atrophy and fibrosis of the cortical nerve cells.

7 Jackson Barr. The Circulation of the Cerebrospinal Fluid Its Importance in Acute Cranial Injury T. A. M. A. 79: 1394-1396 (Oct. 21) 1922

1901-1905 was 16.4 per hundred thousand, while during the period 1926-1930 it averaged 17.9 and was therefore only 1.5 points higher, but the similarly adjusted death rates in the female sex for these two quinquennia were respectively 18.2 and 32.4, an increase of 78 per cent

Among men under 55 in New York City, even a slight decline in the mortality from diabetes has been noticeable during the thirty-year period under consideration, but it has been counterbalanced by a fairly definite tendency for higher death rates among those past that age (chart 3)

Among females, increases in the diabetes death rate have been definite after women are past the age of 45 in the group 45-55 years, in a comparison of the rates of the first quinquennium of the century with the recent

deaths, in 1901 the proportion was 0.6 per cent. In chart 1 may be studied figures of the mortality charged annually since 1910 to diabetes in New York City

REVERSAL OF SEX RATIO

Thirty years ago, in New York City, the male deaths from diabetes, 269 in 1901, still exceeded definitely those of the female sex, which numbered that same year 234, but in 1931 the 1,288 deaths among females were twice as numerous as the deaths in the male sex, 633. It is interesting to note that in New York City and in the United States this reversal of the proportion of diabetes mortality in the two sexes took place practically at the end of the last century or at the beginning of the present one, whereas in England and Wales it first became pronounced in the early twenties, namely, appearing, as the registrar-general noted, "with some suddenness especially in 1920"

In general, it is usually with the consumption of food and of sugar particularly that diabetes mortality is reckoned to be linked, but as to the greater rate of increase in the female sex lately, opinions have to be more speculative. A thought in conjunction with this situation that one could entertain might refer to the earlier liberation in America and more noticeable

Chart 2—Diabetes deaths according to sex and age in New York City since 1901

one, there is noted an increase in the diabetes death rate from 30 to 50 per hundred thousand or by 60 per cent, among women between 55 and 65, the rate has practically doubled, namely, from 93 to 181, among those between 65 and 75, it has risen from 154 to 333, or by 116 per cent, and among those 75 years of age and over, the rates have been high, namely, from 180 to 282, or a rise of only 35 per cent, naturally interfered with by other intercurrent conditions common to advanced age

In 1901, in New York City, the 503 deaths recorded as due to diabetes were only 0.7 per cent of the total 70,720 deaths from all causes that year, in 1931 this disease was held responsible for 1,921 deaths in the grand total of 77,418, or for 2.4 per cent, a proportion three times as great as previously. During the year 1930, in the United States Registration Area, the mortality from diabetes comprised 1.7 per cent of all

Average Annual Mortality from Diabetes in New York City During Successive Quinquennia Since 1901*

release from physical labor and home drudgery, lightened by the "machine age," that the so-called modern woman enjoys here. Has that change of habits taken place sooner in the United States than in England? Is diabetes a concomitant of reduced physical exercise—throwing a greater load for necessary elimination on the internal organs?

INSULIN AND MORTALITY

The influence of insulin,² if any, beyond postponement of the age at which death from diabetes follows, cannot be said to be striking on the mortality in New York City, though it may have checked a greater rate of increase. In the male sex, the death rate during the last thirty-year period was indeed highest in 1922, namely, 20 per thousand—though this was somewhat of an isolated spurt—and it did come down in 1923 to 17, and to 14 in 1924, but thereafter a comparative slight rate of increase was resumed, as shown in the inserts in chart 3. Among females, even with the appearance of a decrease in 1924 and 1925, the death rate continued to increase thereafter and, for that matter, since 1926 has been sharply going up.

More marked and definite than insulin, however, is, as is well known, the influence of comparative shortage of food on the mortality of either sex. Thus, for instance, in 1918 and 1919 the number of deaths both among men and among women was noticeably reduced,

2 Insulin was introduced in 1922

again, following the short period of unemployment in the early twenties, another recession occurred and the mortality came down in 1924 and in 1925. For that matter it seems, generally speaking, that for some three years following a comparative food shortage diabetes mortality is reduced, but thereafter its course is resumed. Strangely, so far, namely, in both 1930 and 1931 in New York City, even after the burst in 1929 of the so-called bubble of prosperity, diabetes mortality has continued to rise. The course of it during the next two or three years is still problematic.

JEWS AND DIABETES

Bolduan and Weiner,³ in their recent study of New York City mortality among Jews and non-Jews, in the white population, brought out clearly the striking difference between the two groups as regards diabetes

sex of this group and 25.7 among their females. These comparatively lower diabetes rates for the colored group, however, must be taken with some reserve, as its age composition here is probably different and younger, on an average, than the white group. Differences in diabetes mortality between the two sexes, however, are practically similar among the colored races and with the white race.

SUMMARY

In New York City, from 1901 to 1931, the recorded mortality from diabetes has risen from 503 to 1,921, or, from a crude rate of 14.2 per hundred thousand to 27.1, and from a standardized death rate of 17.3 to 27.9.

Among females, diabetes mortality has increased more rapidly, the death rate, standardized, having been 16.3 in 1901 and 35.5 in 1931, whereas among males,

Chart 3—Diabetic death rate annual and by five year periods in the two sexes in New York City since 1901

thus for instance, in 1931 among non-Jews, in the age group 50-60 this disease was responsible for slightly less than 20 deaths per thousand from all causes, whereas among Jews it was chargeable for 40 per thousand, among non-Jewish women between 60 and 65 there were over 65 deaths on an average from diabetes among each thousand deaths from all causes, but among Jewish women of the same age the mortality was nearly twice as high, or about 115 deaths from diabetes per thousand from all causes.

In New York City the mortality from diabetes among the colored races is at a lower rate than among the white race. For instance, in 1931 while the crude death rate of the entire population from diabetes was 27.1 per hundred thousand among the colored races mostly Negroes it was 18.4 being 11.1 in the male

adjusted similarly, it has changed only from 18.3 to 19.0. Among men past 55, the diabetes death rate in New York City has, however, measurably increased, among women, the rise begins earlier, namely, at 45 years of age, and their death rate has gone up markedly.

The population of New York City is almost 30 per cent Jewish, and in this racial group the proportion of diabetic deaths to all other causes exceeds markedly that of the non-Jewish white population of the city. Among the colored races, the death rate has been lower than in the white race, but the same excess among females has been noted in both groups.

While a comparative shortage of food during the World War has here too been followed by some diminution of diabetes mortality, the use of insulin since 1923 has been accompanied by only a slight recession which has been entirely lost since

Clinical Notes, Suggestions and New Instruments

OPEN SAFETY PIN IN THE STOMACH OF A TWO MONTHS OLD BABY

HARRY OTTIN, M.D., SPRINGFIELD, ILL.

A baby girl, aged 2 months, swallowed an open safety pin, Oct. 4, 1932. The child had been crying, and to quiet it the mother pressed it against her bosom. As she did so the child's open mouth was pressed against the safety pin in the mother's dress. It promptly swallowed the pin.

The use of the roentgenograph the next day and of the fluoroscope each succeeding day for six days showed the open safety pin in the cardiac end of the stomach in the same position as when swallowed. During these days the child was regularly nursed and was given bread and milk, potatoes, and cooked cereals. In addition a barium meal was given definitely to locate the safety pin in the stomach, and it was also hoped that the barium might carry the pin out of the stomach with it. October 10, it was decided to use operative intervention because it was feared that the pin might cause perforation and peritonitis.

A laparotomy was done under ether anesthesia, through an incision to the left of the median line just below the costal margin. The pin, which was located in the cardiac end of the stomach high up, was manipulated to the fundus and carefully closed through the stomach wall. The advisability of stopping treatment at this point was considered, as well as of removing the pin by gastrotomy. Both plans were abandoned in favor of another idea, which had presented itself previous to the time an operation had been decided on. This method was attempted and it was successful. A small stomach tube was passed from the mouth through the esophagus into the child's stomach, and the closed safety pin manipulated into the end of the stomach tube, which was then withdrawn with the safety pin in it. After this the abdominal wound was closed in layers without drainage. The wound healed by primary union,

Open safety pin in cardiac end of stomach after barium sulphate meal

and the skin sutures were removed on the seventh day. The child made an uneventful recovery.

There are two unusual things about this case.

First, it is unusual to have a child so young swallow a safety pin.

Second, the simple method of closing the safety pin through the stomach wall, then of passing the closed safety pin into the stomach tube, and of removing the pin was accomplished without opening the stomach.

A DRESSING FOR HEMATOMA OF THE EAR

L. K. FERGUSON, M.D., PHILADELPHIA

Associate in Surgery, University of Pennsylvania School of Medicine

Hematoma of the ear is seen very frequently at the Surgical Out-Patient Department, and at the Student Health Service of the University of Pennsylvania, where wrestlers and boxers of the university squads are cared for. These hematomas are often treated soon after they appear and while the blood is still liquid, so that aspiration is an easy procedure in most

View of dressing from behind, showing how the cast encloses the auricle.

cases. The more difficult part of the treatment is the application of a pressure dressing that will prevent recurrence. Although textbooks state that a snug bandage over the ear is sufficient, my experience has been that recurrence almost invariably takes place with such treatment. Some authors have suggested the use of plaster molded pressure bandages. These have been found to be cumbersome, and many students are content to have a cauliflower ear rather than to wear a large dressing that surrounds the head.

A dressing is here presented that has proved successful in preventing recurrence and is neither cumbersome nor particularly unsightly. After aspiration of the hematoma, cotton, soaked in collodion, is molded to the auricle so as to fit the depressions in the ear. While the collodion is drying, pressure over the area of the hematoma is maintained by means of a hairpin, which may be bent as shown in the illustration. The hairpin may be removed after twenty-four hours, the dry collodion forming a firm pressure dressing, which may be removed in five or six days.

CHRONIC ACETANILID POISONING

LUTHER C. FISHER, M.D., MINNEAPOLIS

Two decades ago, acute and chronic acetanilid poisoning from the use of various "headache powders" was quite common. Following the elimination of the more dangerous proprietary preparations from the market and the widespread propaganda against their use generally, instances of acetanilid poisoning have greatly diminished. Nevertheless, an occasional case of acute poisoning is still encountered resulting from an overdose or following a usual dose in patients with an idiosyncrasy for the drug. Chronic poisoning is apparently rarer and for this reason the following case is reported.

The continued use of medicaments containing acetanilid or acetphenetidin may result in the habituation of the patient to the drug. Sudden discontinuance of the drug is frequently followed by "withdrawal" symptoms. The habituation, the

From the Department of Medicine, University Hospital, University of Minnesota Medical School

clinical signs and symptoms and laboratory characteristics of the poisoning, and the subsequent withdrawal symptoms are exemplified in the case here reported

REPORT OF CASE

R H, a man, aged 47, visited the outpatient department of the University Hospital, June 5, 1928, complaining of cough, expectoration, pain in the left chest, headache, weakness and weight loss of 20 pounds (9 Kg) in a month. Fine rales were present over both apexes. He was sent to a tuberculosis sanatorium, where tubercle bacilli were found in the sputum. He gradually improved and was discharged a year later, in June, 1929.

He was observed in the outpatient department but finally entered the University Hospital in September, 1929, for tiredness, weakness, loss of the weight that had been regained at the sanatorium, cough with expectoration of from 60 to 90 cc. of sputum each day, and dyspnea on exertion. The patient was markedly cyanotic and stated that the blueness had been present for three years, although it was not particularly striking until the time of the present admission. The only abnormal finding was the presence of rales in the bases of both lungs. Roentgen examination revealed healed tuberculosis in both apexes and minimal bronchiectasis in the left base. He was discharged and treated as an outpatient, with injections of iodized poppy-seed oil.

In November, 1929, during a reexamination at the tuberculosis sanatorium, a physician noted "flushed features with a reddish cyanotic countenance." During the following two years he visited the outpatient department from time to time and finally reentered the hospital, Sept. 23, 1932, in the medical service of Dr H A Reimann. At this time he was almost unable to walk because of extreme weakness. He coughed and raised from 30 to 60 cc of sputum daily. Headache, which had been severe, became worse and was almost constantly present. There was a marked tendency to sleep. He responded very slowly to questions and appeared to be confused at times. Anorexia, epigastric discomfort after eating, constipation and frequency of urination were present.

On physical examination the most striking feature was the marked cyanosis of a peculiar violaceous or lavender hue, of the face. The color was especially well shown in the infra-orbital regions, mucous membranes, nipples and finger nails. There was weakness of all muscles, coarse tremor of the tongue and hands and some incoordination. Examination of the heart and lungs gave negative results. His mouth temperature varied from 35.5 C (96 F) to 36.7 C (98 F), seldom reaching 37 C (98.6 F). The pulse rate varied from 60 to 100 but usually hovered about 78. The respirations varied from 14 to 20 per minute but usually were 18 per minute.

The laboratory data revealed urine, normal hemoglobin, 80 per cent (Sahl), erythrocytes 4,300,000, leukocytes 12,600, neutrophils 90 per cent, lymphocytes 8 per cent, eosinophils, 2 per cent, blood platelets 177,000, icterus index 8 units and the nonprotein nitrogen 37 mg. The carbon dioxide combining power of the plasma was 51 volumes per cent. Roentgen examination revealed healed tuberculosis but no evidence of bronchiectasis after injection of iodized poppy seed oil. An electrocardiogram showed no abnormalities.

The presence of striking cyanosis in the absence of evidence of heart or lung disease suggested the possibility of some type of aniline drug poisoning. On questioning the patient admitted taking anacin tablets (each tablet containing 0.2 Gm or 3 grains of acetphenetidin) in large numbers over a long period of time. A few days later he volunteered further information of taking bromoseltzer (each gram containing 0.042 Gm of acetanilid) continually. The habit began twenty years ago in 1912 when he used bromoseltzer for occasional headaches. The headaches increased in severity and frequency so that by 1917 he took a table-spoonful two or three times a day. In 1926 it was noted that his color was not good and his physician warned him about the habit. Despite the advice he began taking five or six anacin tablets a day when bromoseltzer was not available but the tablets failed to satisfy the craving. When he applied to the outpatient department in 1928 he was apparently taking from 90 to 180 Gm of bromoseltzer (175 to 350 Gm of acetanilid) daily. During hospitalization at the sanatorium the drug was not available and the craving

which developed passed off in a few weeks. The patient apparently made no mention of the condition. After discharge, the drugs were resumed, and at the time of the present admission the estimated intake was 200 Gm of "bromoseltzer" (acetanilid, 84 Gm) and from twelve to twenty-four "anacin" tablets (acetphenetidin, from 24 to 48 Gm) daily.

After a diagnosis of chronic acetanilid and acetphenetidin poisoning had been made, spectroscopic examination of the blood revealed the presence of methemoglobin in large amounts (Dr C O Hansen). The blood itself was of a peculiar dark brownish color.

A week after hospitalization, after the drugs had been discontinued, marked mental symptoms gradually developed. The patient became confused, disturbed and irrational, and soiled his clothing with urine and feces. He developed ideas of reference and persecution, but no restraint was necessary. In the course of a week or two the mental symptoms gradually disappeared. Two months after the withdrawal of the drugs he felt much better, gained 15 pounds (6.8 Kg) and was stronger. The tremor had disappeared. There were no headaches and the cyanosis, although still present, was greatly diminished.

COMMENT

The case illustrates the enormous amounts of acetanilid and acetphenetidin to which a patient can become accustomed. Webster¹ states that, in susceptible individuals, death from acute poisoning may occur after the intake of from 0.3 Gm (5 grains) to 0.6 Gm (10 grains) of acetanilid, but recovery has followed doses as large as 28 Gm (420 grains). Doses of 0.3 Gm, 0.6 Gm and 1 Gm of acetphenetidin have proved fatal. My patient was apparently taking as much as 8 Gm of acetanilid and 3 Gm of acetphenetidin daily over a long period. The typical symptoms and signs of chronic poisoning developed, namely, cyanosis, weakness, subnormal temperature, mental and physical debility, and methemoglobinemia. Typical withdrawal symptoms appeared when the drugs were withheld. Recovery followed.

An interesting feature of the case is that the cause of the cyanosis was overlooked so long and by so many physicians. The cyanosis was presumably attributed to tuberculosis at one time and subsequently to nonexistent bronchiectasis. It appears to be important to inquire into the drug habit of any patient exhibiting marked or peculiar general cyanosis in the absence of demonstrable pulmonary or cardiovascular disease.

ARSENIC POISONING CAUSED BY A MOUTHWASH CONTAINING SOLUTION OF POTASSIUM ARSENITE

HARRY LOWENBURG MD AND MEYER NAIDE MD
PHILADELPHIA

D G, a white girl aged 10 years was admitted July 20, 1932 with Vincent's infection of the mouth of eleven days' duration. Symptoms of note prior to admission included anorexia, fetor oris, fever and anuria. Bitter complaint of vomiting and gagging continuous nausea and inability to retain anything even water, was made by the mother. The patient had received an injection of Thio-Bismol (sodium bismuth thio glycollate) into the buttock, a local application of neoarsphenamine (0.4 Gm in aqueous solution), and the following mouthwash:

1) Vinis specueuanae	Oz. ii
Glycerin	Dr. iv
Liq. arsenicalis (Fowler's solution) q. s.	ad Oz. iv

On admission the temperature, pulse and respiration were 98.6, 100 and 25 respectively. The blood pressure was 105 systolic, 70 diastolic. The prominent features on examination were a shallow lingual ulcer, moderate cervical lymphadenopathy and right-sided abdominal tenderness. The heart and lungs presented no abnormalities. There was no edema, and the evidences were normal.

The admission diagnoses were (1) Vincent's infection and (2) anuria (of unknown origin).

¹ Webster R W. *Legal Medicine and Toxicology*. Philadelphia: W B Saunders Company, 1930, p. 82.
From the Pediatric Service of Dr Harry Lowenberg, at the Mount Sinai Hospital.

On the day of admission the blood examination showed 80 per cent hemoglobin, 4,520,000 red cells and 22,400 white cells, of which 87 per cent were polymorphonuclears, 11 per cent small monocytes and 2 per cent large monocytes. The blood urea nitrogen was 143 mg per hundred cubic centimeters, creatinine 8.4 and blood sugar, 122. The Wassermann reaction (Kolmer and Kahn) was negative.

As no urine had been voided for three days, the patient was catheterized July 21, and the bladder was found to be empty. Twelve hours later another catheterization yielded 4 cc of turbid urine containing a cloud of albumin. In searching for the etiology of the anuria, one of us (H. L.) suggested that the drug injected into the buttock prior to admission might have been an arsenic compound which was given for the Vincent's infection. (At this time the previous medication was still unknown to us.)

July 22 the presence of arsenic was demonstrated in the urine by the Gutzeit test. This was corroborated the following day in another specimen of urine. While this procedure led to a correct solution of the problem, the source of the arsenic was found to be elsewhere.

Treatment at this time included the forcing of fluids by mouth, hypodermoclysis (500 cc of physiologic solution of sodium chloride every eight hours), 50 per cent dextrose and 10 per cent magnesium sulphate intravenously, hot applications, and alkalis internally. The use of sodium thiosulphate was considered, but the duration of the illness and the rapid subjective recovery of the patient led us to believe that it was unnecessary.

The vomiting ceased after twenty-four hours in the hospital and the clinical condition improved gradually. The blood urea nitrogen had fallen from 143 mg to 129 by July 26, and to 104 mg July 28. On the latter date, arsenic could no longer be demonstrated in the urine. The urinary output improved so strikingly, as shown in the chart, that, in spite of the evident urea retention, the patient was discharged to the care of her private physician. The patient was entirely free of symptoms six weeks later.

COMMENT

This case, as briefly outlined in sequence, was not actually solved with such apparent simplicity. It required a detailed correspondence with physicians in a distant city, who had treated the patient originally, to determine the possible relationship between the anuria, the vomiting, the arsenic present in the urine and previously administered drugs.

The Thio-Bismol (Parke, Davis & Co.), the drug that had been injected into the buttocks, contains no arsenic in its formula, this fact being corroborated by a negative Gutzeit test.

It was further learned that the neoarsphenamine had been well diluted and applied lightly to the gums only once.

The solution of potassium arsenite in the mouth wash contained $7\frac{1}{2}$ grains (0.47 Gm) of arsenic trioxide. Holland¹ reports a case of arsenic poisoning which proved fatal after a quantity of solution of potassium arsenite that contained only 2 grains (0.13 Gm) of arsenic trioxide had been taken.

SUMMARY

- 1 Arsenic poisoning may follow the use of easily absorbable preparations of arsenic when they are used as mouth washes.
- 2 The practice is pernicious and unnecessary.
- 3 Equally good results are attained in Vincent's and other mouth infections by the use of simple cleansing and oxidizing agents.
- 4 Arsenic poisoning should be suspected in all cases of persistent vomiting, especially when associated with anuria and a history of mouth infection.
- 5 The high urea nitrogen was probably more relative (to blood volume) than absolute and was due to blood concentration and probably did not represent an actual increased retention. Only in this way can be explained the absence of drowsiness, coma and convulsions.

325 South Seventeenth Street—Mount Sinai Hospital

A CASE OF MENSTRUAL ALLERGY

W. T. HARRISON, M.D., WASHINGTON, D. C.
Surgeon, United States Public Health Service

This case is reported in view of the unusual nature of the allergy and the possibility that similar instances of hypersensitivity may be fairly common.

Mrs. C., white, aged 23, seen Feb. 12, 1932, complained of giant urticaria since the preceding November. The lesions were from 4 to 8 inches in diameter and occurred chiefly on the face and extremities, but appeared on any part of the body. She was sometimes free for as long as two weeks, again she would have two or three attacks in twenty-four hours. At the age of 16 she had one attack after eating strawberries. She was married at 18 and had her first child at 21, and a second child eighteen months later. Labor was normal. The menses reappeared when the second child was 5 months old and were accompanied by an attack of giant hives. She also noticed local irritation during the menstrual period, so marked that, opposed to her usual custom, she was disinclined to walk for any considerable distance. A maternal aunt had autumnal fever. The patient gave an indefinite history of summer cold during 1931. She had had the usual diseases of childhood.

When tested cutaneously with the common foods and usual pollens of the Washington district, she showed a questionable reaction to coconut and a definite reaction to egg white. Removal of eggs and coconut from the diet and the use of castile soap during an intermenstrual period resulted in complete freedom from hives. The patient was next directed to take daily small increasing doses of egg white, and succeeded in increasing her tolerance so that she could take one egg each day without symptoms. During the succeeding menstrual period, hives reappeared as severe as before and disappeared with the menses, to reappear with the next.

A well worn and washed cotton cloth was used as a menstrual pad and when saturated was extracted for seven days at 7 C in salt solution containing 0.5 per cent phenol. The extract was passed through a Berkefeld filter and 0.05 cc of a 1 in 4 dilution was injected intracutaneously with suitable control. A small wheal with irregular edges, surrounded by a zone of hyperemia, appeared within ten minutes. Five-hundredths cubic centimeter of the concentrated extract was next injected and was followed by a large wheal 2 cm in diameter surrounded by a large erythematous zone and accompanied by heat and itching. One week later, 0.1 cc of the concentrated extract was injected subcutaneously and the patient was observed for fifteen minutes before leaving the

¹ Holland, J. W. Textbook of Medical Chemistry and Toxicology. Philadelphia: W. B. Saunders Company, 1908.

COUNCIL ON PHYSICAL THERAPY

VOLUME 100
NUMBER 10

laboratory. Shortly after leaving, the patient noticed some palpitation and difficulty in breathing. Large hives appeared on the back and on the legs during the next hour and persisted for two days. After this quite evident overdose, the extract was diluted 1:10 and the dose reduced to 0.2 cc, then it was gradually increased twice weekly until at the end of two months 2 cc of the concentrated extract could be injected with only local redness and swelling.

Two days after the seventh desensitizing dose (0.5 cc of the concentrated extract) the menses appeared and were accompanied by a severe attack of hives and considerable local edema and irritation. At the end of the period the injections were resumed and by the next menstrual period a dose of 15 cc of the concentrated extract had been given. There were no hives during this menstrual period and only slight local irritation. The injections were continued weekly during the next six weeks, the maximum dose (2 cc) being given and discontinued with instructions to report for additional treatment if hives reappeared. At the last report, three menstrual periods had passed with no hives and no local edema or irritation. Caution is still practiced with regard to the ingestion of eggs, not more than one egg being taken in one day.

The appearance during the menstrual period of generalized hives with local edema and irritation, all of which were relieved by gradually ascending doses of a menstrual extract to which the patient is skin sensitive, seems to incriminate some factor connected with the menstrual material as the allergin responsible for the patient's symptoms. She is not sensitive to her own blood serum or to the serum of one other person.

National Institute of Health

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY OF THE AMERICAN MEDICAL ASSOCIATION HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
H. A. CARTER, Secretary

HEIDBRINK OXYGEN TENTS, MODELS 32 AND 32R, ACCEPTABLE

The Heidbrink Oxygen Tents, Models 32 and 32R, are manufactured by the Heidbrink Company, Minneapolis. The manufacturer declares that the tents will provide a means of administering oxygen therapy at hospitals or clinics.

The hood of Model 32 is constructed of heavy rubber sheeting rubberized on both sides. The windows are cellulose acetate (not inflammable). There are eight windows in all and they are placed on the four sides of the hood and on the top. The hood is made with an extra long skirt with flares on the corners, and the center panels allow plenty of material for tucking under the mattress. There are two sleeves for passing food, water or other items into the tent. All the seams on the inside of the hood are covered which makes it as nearly air tight as it is possible to construct an enclosure of this kind.

Fig. 1—Model 32

The hood is supported on three spring hangers. The spring hangers prevent the tearing of the material when a sudden strain is exerted. The hangers are mounted on a bar and are movable. The hood is wide enough to cover the full width of the standard hospital bed and can be collapsed to one half this width, thus fitting an infant's crib. When not in use the hood can be collapsed to a 6 inch width for convenient storage.

The hood is mounted on a horizontal bar, which tilts to an angle of 45 degrees. The bottom of the skirt has tabs with eyelets so that the bottom can be luted up. When the entire hood is tilted it can be placed over the patient by one nurse. The tilting bar is equipped with a chain and hook and when tilted to the desired angle it can be fastened there while the apparatus is adjusted to the bed.

The icebox is large and is insulated on top, bottom and all sides. It has a completely removable lid with a soft rubber gasket. When the lid is fastened down by means of the lock arm, it provides a tight seal. The icebox holds 65 pounds of ice. The box is provided with a half inch drain and trap with clean-out plug.

The motor and blower have been designed particularly for oxygen tent use. The motor possesses a low speed. It is mounted completely cushioned in rubber, which reduces vibration, and the low speed precludes motor hum.

The blower is also cushioned in rubber. It is of large capacity and the openings are sufficiently large to avoid any restriction of the circulation. The motor blower unit is controlled by a rheostat of the coil type and possesses many different rates of speed.

The soda lime container is easy to get at and is of the removable basket type, which can be carried to a sink or table for filling or emptying. The soda lime container has a damper by means of which all the circulation can be passed through the soda lime, or any part of it, or the entire circulation can be passed around the soda lime without coming into contact with it.

The oxygen delivery is controlled by a pressure regulator of an approved type having an auxiliary needle valve for fine regulation and a gage to show the pressure in the tank. The delivery of oxygen to the patient is indicated on a sight feed flow meter calibrated from 1 to 15 liters per minute. There is no spring mechanism to get out of order. The regulator has an automatic closing emergency flush valve by means of which the entire tent hood can be quickly flushed with oxygen when the patient is first installed.

The apparatus hood has a 14 inch adjustment up and down, and the elevating mechanism can be operated from either side of the equipment. It is directly below the icebox, and the vertical adjustment range is sufficient to accommodate a patient either sitting up or lying down.

The entire equipment is mounted on a single chassis. It accommodates not only the apparatus but also the tank of oxygen. This chassis has large (5 inch) rubber tired ball bearing casters which contribute greatly to the ease of movement. The chassis is built with a lip to accommodate an auxiliary tank truck so that tanks can be installed or removed by any nurse without lifting.

The tank is retained in place by means of a quick-lock arm which swings open wide to receive the tank and then can be locked against it to hold it securely to the apparatus.

Provision is made on the Heidbrink Oxygen Tent for the addition of an attachment for the controlled delivery of carbon dioxide from a tank.

A combination oxygen and carbon dioxide analysis outfit may be obtained at an additional cost. This apparatus will analyze for both oxygen and carbon dioxide concentration from the same sample of air, and the entire procedure can be accomplished in five minutes.

It is claimed that cooling to below 60 degrees is possible regardless of the room temperature and without using the full capacity of the motor blower, and without the addition of rock salt.

The humidity is automatically controlled to desirable limits and, if the tent hood is tucked in around the patient securely, a 50 per cent or better oxygen concentration can be maintained on the flow rate of between 2 and 3 liters per minute. The complete outfit weighs 220 pounds.

The Heidbrink Model 32R has all the operating features of the Model 32 except that the chassis which carries the large oxygen tank is omitted. The ice chest is not quite so large. The Model 32R weighs 160 pounds.

The Council ran several tests on the Model 32. The investigation substantiated the claims made for the unit. The Council on Physical Therapy declares the Heidbrink Oxygen Tents, Models 32 and 32R, eligible for inclusion in the list of accepted devices.

Committee on Foods

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary

BLUE BAR BRAND TOMATO JUICE

Packer—Tugwell and Wiseman, Inc., Modeltown, Niagara County, N. Y.

Description—Canned tomato juice with added salt, retains in high degree the vitamin content of the raw juice.

Manufacture—The tomatoes are grown from a special variety of seeds by independent farmers in the Niagara fruit belt between Rochester and Niagara Falls, N. Y. The harvested vine ripened tomatoes are delivered immediately to the cannery, where they are sorted, washed by agitation in running water, and inspected on endless belts, bruised, green or mushy fruit is discarded. The sound tomatoes are scalded and peeled by hand, undesirable fruit is discarded. The peeled tomatoes, whole or parts, are packed in cans. Juice obtained from this operation provides part of the juice for the canned tomato juice.

Juice is obtained also from whole or parts of the peeled tomatoes by expression by machine consisting of a spiral within a fine cylindric screen. The juice from the several sources is delivered to a filling machine from which it flows into cans. A pellet of salt is added to each can. The filled cans are processed at 82 C, the air incorporated in the juice is substantially removed during the process. The cans are sealed, very little air head space being permitted. The sealed cans are autoclaved for twenty minutes at approximately 100 C and immediately cooled. The complete time between the delivery of the tomatoes and the final processing is about thirty minutes.

Analysis (submitted by manufacturer) —

Moisture	93.9	per cent

Vitamins—Precautions are taken during the manufacture to protect efficiently the natural vitamin content.

Claims of Manufacturer—This tomato juice is a good source of vitamins A and B and an excellent source of vitamin C, for infant feeding and general table use.

WHITE BILLOWS FLOUR (BLEACHED) MARECHAL NEIL FLOUR (BLEACHED)

Manufacturer—Collin County Mill & Elevator Company, McKinney, Texas

Description—An "all purpose" patent flour milled from hard and soft wheats, bleached.

Manufacture—Selected soft and hard wheats are cleaned, washed and tempered by essentially the same procedures as described in THE JOURNAL, June 28, 1932, page 2210. Chosen flour streams are blended, and bleached with a mixture of

benzoyl peroxide and calcium phosphate (1 part to 50,000 parts of flour) and with nitrogen trichloride (one-ninth ounce per 196 pounds).

Claims of Manufacturer—The flour is designed for general home baking.

BARTELDES TENDER NUTRITIOUS TASTY POP CORN

Manufacturer—The Barteldes Seed Company, Lawrence, Kan.

Description—Popcorn in sealed tins and in sacks.

Manufacture—Most of the supply of the corn is grown under contract from selected seed. The matured corn is husked and gathered in October. Some of the gathered corn is brought directly to the warehouse and some is stored in bins or cribs on the farms for later delivery. The corn ears at the warehouse are immediately shelled or stored in rat proof cribs. Before shelling, the ears are inspected and imperfect ears discarded, only thoroughly mature ears in good popping condition are shelled. The shelled corn is run through cleaning machinery and graded to provide a uniformly sized product, an air blast removes light kernels and undesirable material. The prepared pop corn is sealed in tins or packed in bags.

DAVIDSON'S PRIZE SWEDISH RYE BREAD (SLICED)

Manufacturer—Davidson Baking Company, Portland, Ore.

Description—A rye bread made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p. 817) prepared from patent wheat flour, water, "clear" wheat flour, rye flour (two-thirds dark and one-third light rye), syrup, shortening, yeast, salt, rye flavor (combination, in syrup form, of ground caraway and anise seeds with small amount of licorice), malt syrup, and yeast foods containing buttermilk, calcium phosphate and ammonium tartrate, and calcium sulphate, ammonium chloride, sodium chloride and potassium bromate.

Claims of Manufacturer—A rye bread for all table uses.

JEWEL COCOA

Distributor—Jewel Tea Co., Inc., Barrington, Ill.

Description—Cocoa prepared from partially defatted cacao nibs.

Manufacture—The cocoa is purchased on specifications on the basis of flavor, appearance, and conformity with food law requirements. Deliveries are examined by the company laboratory. The cocoa is automatically packed in tins.

Analysis (submitted by manufacturer) —

DAD'S ORIGINAL SCOTCH OATMEAL COOKIES

Manufacturer—Dad's Cookie Company, Memphis, Tenn

Description—Cookies prepared from sucrose, wheat flour, rolled oats, shortening, water, raisins, sodium bicarbonate, salt, cinnamon, vanilla flavor and refined cottonseed oil

Manufacture—Sugar, vanilla flavor, refined cottonseed oil, cinnamon and raisins (ground) are thoroughly mixed (creamed) with the shortening, the oats and water are mixed in, the sugar, soda, salt and flour are thoroughly worked in. The resultant dough is cut by machine (cookie cutter) into cookies weighing 8 ounces to the dozen after baking. The cookies drop on pans and are baked at from 190 to 204 C for eighteen to twenty minutes. The cookies are cooled, packed in boxes and distributed by the company's salesmen

**HEINZ STRAINED GREEN BEANS
(Already Cooked Without Salt or Sugar)**

Manufacturer—H J Heinz Company, Pittsburgh

Description—Canned comminuted and strained cooked green beans retaining in high degree the mineral and vitamin content of the natural product, no added sugar or salt, the coarser fibrous portion is removed

Manufacture—Selected stringless variety green beans are picked at the stage of growth when the bean seed is but slightly developed or when the beans consist mainly of the green tender pod. The beans are sorted washed and inspected, blemishes and overmature or otherwise unsuitable beans are removed. The green beans are placed in a closed cooker and the subsequent processing and packing are essentially the same as described for Heinz Strained Spinach (THE JOURNAL, Feb 25, 1933 p 577)

Analysis (submitted by manufacturer) —

	per cent
Moisture	92.7
Total solids	7.3
Ash	0.5

Carbohydrates other than crude fiber (by difference)	3.7
Calcium (Ca)	0.05
Phosphorus (P)	0.02
Iron (Fe)	0.001

Calories—0.2 per gram 6 per ounce

Claims—The method of preparation efficiently protects the natural vitamin values. The strained beans is a good source of vitamins A, B and G and a fair source of C.

Claims of Manufacturer—For table use of strained green beans but especially intended for infants, children and convalescents and for special smooth diets. Only warming is required for serving. The natural mineral and vitamin values are efficiently retained.

DROMEDARY VELVA DATE

A New Preserve Made from Finest Dromedary Dates

Manufacturer—The Hills Brothers Company, New York City

Description—Date preserves prepared from water, dates, invert sugar, honey and salt

Manufacture—The dates, invert sugar, water and salt are boiled together for about five minutes. The mixture is run through a tomato masher machine to remove pits and skins. The resultant material is concentrated in an open kettle to a desired consistency (74 per cent solids), cooled and admixed

with honey, the mixture is whipped in a mayonnaise mixer until it has attained a definite color and consistency. The final preserve is filled into glass jars which are capped under "partial vacuum" (15 inches of mercury) and processed for twenty minutes at 79 C.

Analysis (submitted by manufacturer) —

CANOVA BRAND PEANUT BUTTER

Manufacturer—Maury Cole Company, Memphis, Tenn., Louisville, Ky., Dallas, Texas, Atlanta, Ga., and Norfolk, Va.

Description—Peanut butter composed of ground peanuts seasoned with salt

Manufacture—Spanish and Virginia shelled peanuts are roasted and cooled, the skins and embryos are removed by machine. The kernels are spread on a continuous belt, and any faulty or undesirable kernels and materials are removed. Definite proportions of the Spanish and Virginia kernels are mixed, salt is automatically added in a definite proportion, and the nuts are ground. The resulting peanut butter is packed in jars, which are sealed in a "vacuum" machine.

Analysis (submitted by manufacturer) —

**FEDERAL HOMELIKE BREAD
(Sliced and Unsliced)**

Manufacturer—Federal Baking Company, Winona, Minn.

Description—A wheat bread made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, page 817), prepared from patent flour, water, sweetened skimmed condensed milk, lard, salt, sucrose, malt syrup, yeast and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate.

Claims of Manufacturer—Conforms to the United States Department of Agriculture definition and standard for white bread.

FISHER'S FARINA

Manufacturer—The Fisher Flouring Mills Company, Seattle.

Description—Purified wheat middlings or endosperm, milled from hard red Montana, Washington and Idaho wheats.

Manufacture—The wheat is cleaned, washed, scoured, tempered and milled. The middlings or farina taken from the first break stock is bolted, passed through purifiers and aspirators, heat treated to destroy any insect infestation, and packed in bags.

Analysis (submitted by manufacturer) —

	per cent
Moisture	10.5
Ash	0.35
Fat (ether extraction method)	0.7
Protein (N \times 5.7)	12.0
Crude fiber	0.2
Carbohydrates other than crude fiber (by difference)	76.2

Calories—3.6 per gram 102 per ounce

Claims of Manufacturer—The farina is almost entirely free from bran or other roughage that may irritate the delicate digestive organs of the infant. It is essentially a carbohydrate food but contains good body building proteins, it forms a smooth breakfast cereal and may be used in many delicious recipes.

THE PARENTAL TRANSMISSION OF VITAMIN A

There is no longer any doubt about the importance of the vitamins for the maintenance of health and well being¹. The study of their specific rôles has been vigorously prosecuted in recent years. The impression is growing that, in contrast to outspoken disorders due to a serious lack of vitamins, there are milder degrees of deficiency which, as McLester has expressed it, may not reach the dignity of disease but nevertheless prevent robust health. The development of an understanding of the functions of vitamins has made it clear that the human organism depends on exogenous sources for these essential food factors. They are not synthesized in the animal body but may be stored there to a varying extent. The problem of the supply of vitamins is thus not merely concerned with the immediate intake in the diet or in some other therapeutic form but also involves the possible availability of reserves in times of unusual stress.

This seems to be particularly true of vitamin A. In their review of the clinical features of vitamin A deficiency, Eusterman and Wilbur² pointed out that until recently the versatility of vitamin A has apparently not been appreciated. A remarkably increasing literature in the last year or two attests its growing importance in the chemistry of food and nutrition, not only in the prevention and treatment of certain ailments of man but, when supplied in liberal proportion, in the maintenance of a satisfactory state of nutrition and a high degree of health and vigor, both in the growing child and in the adult.

The concern about vitamin A thus begins early in life. If the mother passes it on to the offspring in utero, obviously her own resources need to be understood. Later her milk may contain varying amounts of vitamin A that either supplement the store in the infant or represent the chief source of supply in the

early period of growth before other vitamin-bearing foods are available. The possibilities that are involved are quite clear, the facts have for the most part remained in large degree within the bounds of mere conjecture. In a discussion of the transmission of vitamin A from parents to young, Dann³ of the Nutritional Laboratory in Cambridge, England, has noted that there are two ways in which a young mammal may receive an endowment of vitamin A before it is weaned. The vitamin A may pass through the placental barrier into the fetal circulation during gestation, or it may be ingested by the suckling in the colostrum and the milk. Available data concerning this transmission of vitamin A from mother to young are scanty. His own experiments on animals indicate that the vitamin A store of the young cannot be raised by feeding large amounts of carotene, a precursor of vitamin A, to the mother during pregnancy and lactation. Dann concludes that there must be some factor at work limiting quite strictly the amount of vitamin A that can pass through the placental barrier or into the milk.

One naturally inquires whether these observations on animals, notably the rat, may be directly applied to the human mother. The complexity of the placenta varies from species to species, for example, in man and the rat (having a hemochorial placenta) the maternal and fetal bloods come into much more intimate contact than in less highly developed forms. Dann believes that as man and the rat both possess placentas of the same type it may be assumed that the relative importance of the placenta, colostrum and milk for the transmission of vitamin A from mother to young will be similar for the two species. On the basis of this assumption, Dann concludes that the best way of applying vitamin A therapy with the object of giving the child a reserve of vitamin A is to dose it directly. Failing this, the best results may be expected to follow from giving the mother regular fairly high doses of vitamin A during the period of suckling. To give the mother vitamin A during pregnancy will not affect the vitamin store of her child to any extent.

THE ERYTHROCYTE SEDIMENTATION RATE IN DISEASE

In spite of the many studies on the rate of erythrocyte sedimentation, the theory behind the variations in the rate remains clouded. The fundamental basis for this phenomenon, as in the Wassermann reaction, may even remain hidden long after the practical applications have become well understood. It seems to be clear that the normal variation in the rate of red blood cell sedimentation, when tested by any one of several methods, is not great. With the exception of certain physiologic states, such as menstruation and pregnancy, the limits of normal are fairly well defined. The disturbance in,

¹ Present knowledge in this field of study was summarized in the series of articles on vitamins published in THE JOURNAL from June 4 to Aug. 6, 1932.

² Eusterman, G. B., and Wilbur, D. L. Clinical Features of Vitamin A Deficiency, J. A. M. A. 98: 2054 (June 11) 1932.

³ Dann, W. J. The Transmission of Vitamin A from Parents to Young in Mammals, Biochem. J. 26: 1072, 1932.

the stability of the blood that occurs in certain diseases does not seem to be specific. It does appear, however, according to some observers, to parallel with considerable accuracy the degree of activity of the disease.

The performance of this relatively new laboratory procedure is simple, whether by the methods of Westergren or Cutler or by the method of Linzenmeir. The first two methods depend on observing the distance to which the erythrocytes have settled at stated periods of time. The Linzenmeir method differs from the other methods only in recording the time taken for the cells to settle down to a certain point in the calibrated tube. These methods have been checked against one another and have been found to be perfectly comparable. It is therefore safe to allow the choice of method to rest with individual preference, though, for the sake of uniformity, something is to be said for the Cutler method as that most commonly used in this country.

The blood sedimentation test has been used widely already, especially in such conditions as tuberculosis and gynecologic infections. As a routine laboratory procedure supplementary to the more established methods, Cutler¹ feels that the test serves two useful purposes. The first of these is as a diagnostic lead. He feels that it may indicate the presence of serious disease often before it can be recognized on the basis of symptomatology, physical examination or other routine laboratory measures. As a diagnostic gage the test is possibly more accurate in estimating the intensity of disturbance than even fever, the pulse rate or the leukocyte count. If the claims such as those of Cutler continue to be borne out by careful observation and analysis, as has been generally true to the present, a method of inestimable importance has been added to the armamentarium for the study of disease. Thus the difficult and treacherous problem of prognosis in some diseases may be made easier. Also, as a method for estimating the effects of treatment the sedimentation test may prove either a boon or a boomerang.

In another study of the sedimentation test in various diseases, Vickers and Duryee² using the Linzenmeir method, corroborate in general the work of Cutler and others. In the studies reported by Vickers and Duryee there was some overlapping of rapid rates in non-inflammatory conditions and of slow rates in inflammatory ones. Nevertheless the average differences of rate between inflammatory and noninflammatory conditions was striking. Thus pyelitis, active tuberculosis and atrophic arthritis, on the one hand, showed active rates, and, on the other, neurasthenia, 'normal' controls and ureteral stone showed slow rates.

There seems little doubt that the blood sedimentation test is of some value in the recognition, prognosis and

course of certain systemic diseases. The problems concerning this test that remain are important and manifold. Undue enthusiasm should be tempered by the knowledge that many facts connected with its interpretation remain to be elucidated. It is probable that this test will go through the usual cycle of enthusiastic reception and general use before finding its ultimate place as a laboratory procedure of unquestioned but restricted value.

POSTPRANDIAL THIRST

The ability of the normal body to maintain the relative constancy of its fluid matrix has attracted the attention of physiologists since the days of Claude Bernard. Recently, Cannon¹ has written on the mechanisms, as far as they are known, by which the organism preserves its chemical and physiologic equilibrium. Should the blood sugar fall below a critical level, the sympathicosuprarenal apparatus operates to provoke glycogenolysis. If metabolic products are thrown rapidly into the blood stream, as during exercise, the heart, lungs and kidneys respond, and, by rushing oxygen and nutriment to the involved tissues and excreting the waste products, restore the body quickly and efficiently to its normal state. The discomforting sensations of hunger and thirst act as sentinels to give warning of the need for nourishment and are thus considered essential features of the general phenomenon of homeostasis, or the ability of the body to resist change.

Thirst merits especial attention as a factor enabling the organism to maintain its fluid content, and, hence, its metabolic functions. The detailed aspects of water metabolism have been minimized in many treatises on nutrition, probably because an excess intake of water does not appear to be harmful, and under ordinary conditions the daily requirements are satisfied with little attention on the part of the subject. The watery nature of the tissues, however, and the magnitude of the fluid interchanges indicate the importance of water in the body. The daily volume of fluid secreted into the digestive tract, for example, has been estimated by Rowntree to be about 8 liters, or approximately twice the volume of the blood plasma. Moreover, the internal movements of water involve greater quantities than are daily consumed in food and drink combined. Yet chemical analysis of the blood in health reveals only temporary and comparatively minor alterations in its composition. As soon as the tissues need water there occurs a sensation of dryness and stickiness in the mouth. A mild degree of thirst is experienced and is satisfied almost subconsciously several times each day.

The physiology of thirst has been largely clarified by the investigations of Cannon, whose conclusions have been widely accepted. The current theory cor-

relates thirst with a diminished secretion of saliva and other fluids that serve to moisten the mouth and pharynx. With this view the recent investigation of Gregerson and Cannon² are in harmony. These investigators observed that dogs in which the salivary glands had been removed drank no more water than normally, apparently because secretions of the nasal and buccal epithelium sufficed to prevent drying of the mouth and throat. When placed in a room warm enough to cause panting, however, the dogs that had been operated on drank considerably more water than normal animals similarly exposed. The supposition is made that the dog drinks because it needs water and the immediate stimulus is a dry mouth and throat. The data are particularly striking because the subjective factor, which would make observations on persons difficult to interpret, is avoided in these animal experiments.

Further studies³ of the drinking habits of the dog permitted some interesting inferences to be drawn regarding the general nature of thirst. The experimental animals consumed all their water within a few hours after eating regardless of the time of the meal. When water was not made available within this period but was freely offered later, there was a marked reduction in the twenty-four hour intake. The explanation advanced by the Boston investigators is that the after dinner thirst is in response to the drain on the fluid content of the tissues brought about by the copious secretion of digestive juices. This need for water is temporary in that it may be partially or wholly alleviated by the reabsorption of fluids from the alimentary tract.

As a recent article⁴ on the rôle of water in nutrition has stressed, the fluid requirements may be calculated as readily as it is possible to estimate the energy quota. For ordinary purposes it has generally been regarded that a liberal allowance is afforded by 1 cc. of water, from all sources, for each calory of energy. More elaborate computations are involved in determining the irreducible minimum of water when it is desired to limit the intake, as in certain phases of the treatment of cases of pituitary disturbances, some edemas, or epilepsy. To calculate the theoretical requirements, allowance is made for the permanent loss of water by the various excretory channels, including the skin, lungs, kidneys and intestine. Gregerson's data indicate that another source of water loss, the temporary withdrawal of fluid to permit the production of the digestive fluids, must also be considered. The need for water in secretory processes has frequently been included in

expositions on the water economy, but from the desire for completeness rather than from any precise information regarding its importance in calculating the requirements. While the postprandial demand for water may not figure in the final elimination of moisture from the body, it represents a considerable drain on the body's supply of fluid. It would be interesting to know whether the thirst following a meal plays any part in the polydipsia that characterizes certain diseases and metabolic conditions. Physiologically, if verified by subsequent investigation, the phenomenon noted by Gregerson might be considered as much a part of the body's response to a heavy meal as, for example, the alkaline tide of the urine.

Current Comment

SERUM AMYLASE

The diagnosis of disorders of the internal organs of the body is in many instances rendered more than usually difficult because the structures involved are not subject to inspection or ready methods of indirect observation. Abnormalities of gastric function can be investigated by withdrawal of the contents of the stomach and by the application of roentgenologic procedures. None of these devices are applicable in equal degree to such organs as the liver and the pancreas. Consequently the clinical diagnostician is continually searching for new solutions of his difficulties. The examination of the blood is of inestimable help. Chemical examination of the blood has won a place for itself in the clinic. It has displaced the older chemical examination of the urine in several directions, such as for the study of the diabetic state. Biochemists are seeking for knowledge of blood components that may have specific relations to the function of organs as sugar and urea do. This helps to explain the attention that has long been devoted to serum amylase. There is general agreement that this enzyme is derived principally, if not entirely, from the pancreas. Obstruction to the outflow of pancreatic juice, rich in amylase, leads to increase in the content of amylase in the serum, and consequently in the urine. According to the latest observations of Zucker, Newburger and Berg¹ at the Columbia University College of Physicians and Surgeons, in New York, there is little positive evidence that amylase from other organs besides the pancreas can affect the serum amylase. Here it differs from serum lipase, which may easily be increased through tissue injury, particularly in the liver. Through mechanisms inherent in the pancreas, the serum amylase may be either raised or lowered. For example, when the ducts of the pancreas are experimentally ligated, there is a progressive rise for several days in the content of amylase in the blood serum. After excision of the pancreas, the serum amylase falls to less than half the normal value and does not recover. Amylase may be introduced into the gastro-intestinal tract in

large quantities through the advent of saliva The New York investigators have demonstrated, however, that the enzyme is not absorbed from the alimentary tract, hence it cannot affect the evaluation of amylase derived from pancreatic sources Zucker, Newburger and Berg remark that the level of serum amylase can be influenced by a number of factors involving the pancreas No significant change in the serum amylase level has been produced in which the pancreas does not play a dominant part They are inclined to refer all these changes definitely to effects on one of the two mechanisms involved in the external secretory process Whenever outflow or transfer to the intestine is interfered with, the amylase rises This is brought about by mechanical effects, including trauma, or by ether anesthesia. Perhaps these recent observations will help to build a surer foundation for the use of determinations of serum amylase in diagnosis

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES NEW HOSPITALS EDUCATION PUBLIC HEALTH ETC)

ALABAMA

Bill Introduced—S 1111 proposes that physicians practicing in cities or towns of over 5,000 inhabitants pay the state an annual license fee of \$25 that those practicing in cities or towns of less than 5,000 and more than 1,000 inhabitants pay \$10, and that those practicing in all other incorporated towns pay \$5 Cities or towns of over 5,000 inhabitants are not to be permitted to exact an additional annual municipal license fee in excess of \$12.50 and cities or towns of less than 5,000 and more than 1,000 inhabitants are not to exact an annual municipal license fee in excess of \$5

ARIZONA

Bill Enacted—H 64 providing that nothing in the medical practice act is to prohibit the practice of religion or treatment by prayer has been enacted as Chapter 15 Laws 1933

ARKANSAS

Bill Passed—S 203 proposing to accord hospitals treating persons injured through the fault of other persons liens on all rights of action suits judgments compromises or settlements accruing to the injured persons by reason of their injuries has passed the senate

Bill Introduced—S 301 proposes to accord to physicians nurses and hospitals treating persons injured through the fault

of other persons liens on all rights of action, claims, judgments, settlements or compromises accruing to the injured persons by reason of their injuries

CALIFORNIA

Society News—Dr Nathaniel G Alcock, Iowa City, addressed the Los Angeles County Medical Association, January 18, on "Experience with Transurethral Resection of the Prostate." Dr Hermon C Bumpus, Jr, Rochester, Minn, gave a report of punch operations performed during 1932 at the Mayo Clinic—Speakers before the Alameda County Medical Association in Oakland, January 16, included Drs Paul P E Michael on "Essential Pathologic Changes in Cardiac Disease" and Robert T Sutherland, "Treatment of Cardiac Disease" Dr George F McCleary, London, director of medical insurance activities in England, addressed the association, February 23, on medical economics—The San Francisco County Medical Society was addressed, February 7, by George A L Sarton, Sc.D, associate of the Carnegie Institution, Washington, D C, Hitchcock lecturer in history of science, University of California, on "Influence of Arabic Medicine", Drs Clarence Quinan, "Drum Divination," and Miley B Wesson, "George E Goodfellow, Frontier Surgeon and Soldier, 1855-1910"

Osman Sentenced—According to *California and Western Medicine*, E Osman or "Osmun" was recently sentenced to twenty days in the Los Angeles jail for petty theft. On completion of the sentence, Osman was to have been taken to San Diego to answer to a complaint based on an allegation that he had obtained \$3.99 from each of about fifteen physicians on pretense that their names would appear in a publication called "National Insurance Examiner" THE JOURNAL, Jan 23, 1932, page 324, reported that Osman had been calling on physicians posing as a representative of various insurance companies He stated that he had been delegated to select a medical examiner in each town, his reimbursement consisting of \$1 for each specimen of urine sent to the San Diego Laboratories "The American Institute of Life Research, Inc." is the name noted on the receipt which Osman left with the physician after receiving about \$3.50, which, he claimed, was the fee charged for blanks and containers, to be purchased by the selected examiner

COLORADO

Bill Introduced—H 557, to amend the workmen's compensation act, proposes, in effect, to permit "non-medical doctors" to render the medical treatment which employers must supply injured employees

Society News—Dr Roy P Forbes, Denver, gave a demonstration of the Mantoux test for tuberculosis before the Boulder County Medical Society in Longmont, Dec 8, 1932 and Dr Frank B Stephenson, Denver, spoke on tuberculosis in children—The Crowley County Medical Society at its meeting, Dec 20, 1932, heard a paper by Dr George B M Baker, Rocky Ford, on influenza—Dr William M Bane, Denver, discussed modern methods of treatment of diseases of the eye before the Fremont County Medical Society recently, and Dr James M Shields, Denver, showed photographs illustrating normal and pathologic conditions of the internal eye.—Speakers before the Kit Carson County Medical Society, December 5 at Genoa, included Drs Harold R McKeen and Harold B Henderson, Denver, on treatment of skull fractures and practical points in modern obstetrics, respectively—Dr Charles A Rymer, Denver, talked on "Psychiatry and Mental Hygiene and Their Relations to the Physician," December 7 before the Larimer County Medical Society in Berthoud—A recent meeting of the Otero County Medical Society was addressed by Dr Benjamin F Jackson Fort Lyon, on "Simplified Ophthalmoscopic Examination for the General Practitioner"—A symposium on shock was conducted before the Medical Society of the City and County of Denver, January 17 by Drs Thomas D Cunningham, William W Haggart, William C Black, Jr, and Richard W Whitehead.

CONNECTICUT

Bills Introduced—H 520 and H 769 propose to make hospital records admissible in evidence so far as they relate to the medical or surgical treatment or medical history of persons treated therein but nothing contained in such records which has reference to the question of liability is to be admissible.

Society News—Dr Edward Rist University of Paris France addressed the Hartford Medical Society February 14 on pulmonary diseases—The Waterbury Medical Society was addressed February 9, by Drs Temple S Fay Phila-

delphia, and Charles L. Larkin, Waterbury, on "Cerebral Symptoms in General Practice" and "Common Mistakes in the Diagnosis and Treatment of Diseases of Women," respectively — Dr. John L. Rice, health officer of New Haven, was elected president of the Connecticut Public Health Association at its annual meeting in New Britain, January 26, succeeding Dr. William F. Wild, health officer of Bridgeport.

Tuberculosis Prevention — In a special program of tuberculosis prevention work, sponsored by the New Haven Department of Health and the board of education recently, roentgenograms of the chest were taken of 6,400 children of high school and upper grade ages. Except in the cases of ninety pupils, the cost was paid by the respective parents. The roentgenograms are now being studied by the bureau of tuberculosis, it was reported, and will be returned to the pupils after the family physician has been informed of the results. Among 700 high school children already studied, it was shown that the disease was suspected in 55 per cent, while childhood and adult types were manifest in 32 per cent and 0.4 per cent, respectively.

DELAWARE

Bill Introduced — H. 278, to amend the narcotic drug act, proposes to prohibit the sale of "cannabis indica, cannabis americana, cannabis sativa, loco weed, Canadian hemp, marijuana, marajuana, and all allied drugs of the same botanical family," except on the prescription of a licensed physician, dentist or veterinarian.

Health at Wilmington — Telegraphic reports to the U. S. Department of Commerce from eighty-five cities with a total population of 37 million, for the week ended February 25, indicate that the highest mortality rate (21) appears for Wilmington, and the rate for the group of cities as a whole, 12.3. The mortality rate for Wilmington for the corresponding period last year was 32.9, and for the group of cities, 12.9. The annual rate for eighty-five cities for the eight weeks of 1933 was 12.6, as against a rate of 12.1 for the corresponding period of the previous year. Caution should be used in the interpretation of weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits or that they have a large Negro population may tend to increase the death rate.

FLORIDA

Personal — Dr. Thaddeus S. Troy, Lake City, was appointed chief medical officer for the new veterans' home at St. Petersburg, effective January 1.

New Quarantine Station — Arrangements have been made for the transfer of the Tampa quarantine station at Mullet Key to property located on Gadsden Point, donated by the Tampa chamber of commerce. It was stated that the government had accepted the property to replace the present quarantine station at Mullet Key and would expend about \$100,000 in building and equipment.

Society Sponsors Safety Campaign — The Duval County Medical Society is sponsoring a safety campaign to reduce automobile fatalities in Jacksonville and Duval County. The educational program will be carried on through the radio, the press, motion pictures and messages to civic organizations. Careful driving will be emphasized in the society's messages to the public, according to the *Journal of the Florida Medical Association*.

GEORGIA

Personal — Dr. Daniel M. Bradley, Waycross, has been elected commissioner of health of Ware County — Dr. Webb Conn, Brunswick, has been elected health commissioner for Glynn County.

Bill Introduced — S. 226 proposes to levy an annual occupational tax of \$10 on all practicing physicians. Physicians failing to pay the annual tax are not to practice during the period of their delinquency. No municipal corporation or county may levy an additional occupational tax.

ILLINOIS

Bill Introduced — S. 296 proposes to levy an annual tax on physicians, amounting to 15 per cent of the difference between gross receipts from practice and \$1,200.

Society News — Dr. Joseph W. Larimore, St. Louis, addressed the Adams County Medical Society in Quincy, February 13, on "Differential Diagnosis of Peptic Ulcer." — Speakers before the Pike County Medical Society in Pittsfield, January 26, were Drs. Don W. Deal, on "Nonsurgical

Abdominal Pains", Walter G. Bam, "Diagnosis and Treatment of the Thymus," and Hermon H. Cole, "Streptococcus Empyema." All were from Springfield — Dr. David S. Hillis, Chicago, addressed the Peoria City Medical Society, February 21, on "Diagnosis and Management of Disproportion Between the Head and the Pelvis."

CHICAGO

Dr. Mixer to Give McArthur Lecture — Dr. Charles G. Mixer, Boston, will deliver the ninth Lewis Linn McArthur Lecture of the Frank Billings Foundation of the Institute of Medicine of Chicago, March 24. His subject will be "Meckel's Diverticulum and Its Surgical Significance."

State University Sponsors Program — The following physicians will present a program before the Chicago Medical Society, March 15, under the sponsorship of the University of Illinois College of Medicine:

Frederick H. Falls, Management of Eclampsia and Toxemia
William H. Browne, Use of Anterior Pituitary Prohormone in Menstrual Disorders

Bernard Fantus, Use of Vehicles for Medicine (with demonstration)
Isadore P. Bronstein, Hypothyroidism and Cretinism in Children—Consideration of Special Problems

Memorial Bookshelf — One section of the library of Michael Reese Hospital has been dedicated as a memorial to Dr. Heliodor Schiller, former member of the staff, who died Oct. 20, 1932. Volumes on surgery from Dr. Schiller's library form the nucleus of the section known as the "Schiller Memorial Bookshelf." A bronze plaque has been placed over the section. Contributions from staff members, friends, relatives and patients will provide a fund, the income from which will be used for the purchase of additional books on surgery.

Children Examined for Tuberculosis — Under a plan worked out by the Chicago Tuberculosis Institute and Superintendent of Schools William J. Bogan, the tuberculosis testing of school children in Chicago was begun recently. The test is performed only on children who present a signed statement from their parents authorizing it. The Pirquet skin test is given, roentgenograms will be made of positive reactors and records kept of all cases. When conditions are found which require observation or treatment, parents will be notified and asked that the pupil be placed under the care of a physician. Case records will be available for the information of family physicians. The work was begun in the Lake View High School, and it is expected to continue it in other schools.

INDIANA

Resolutions of Secretaries — A resolution opposing "any form of group hospitalization not fostered by the county medical societies" was adopted at the recent annual secretaries' conference of the Indiana State Medical Association. Another resolution endorsing the minority report of the Committee on the Costs of Medical Care was adopted. Speakers at the session in Indianapolis included Drs. Edward H. Cary, Dallas, Texas, President, American Medical Association, and J. Milton Robb, Detroit, president of the Michigan State Medical Society.

Bills Introduced — S. 139 proposes to repeal the laws relating to the possession and distribution of narcotic drugs and to enact the uniform narcotic drug act. H. 414 proposes to authorize public school authorities to order the examination of school children by licensed physicians and if the examinations disclose the presence of contagious, infectious or communicable diseases to exclude afflicted children from school during the course of such diseases. H. 435 proposes to repeal the law authorizing the sexual sterilization of certain socially inadequate inmates of state institutions. S. 270 proposes to create an independent board of chiropractic examiners and to regulate the practice of chiropractic. Chiropractic is defined as "the science of locating and correcting any interference with nerve transmission and expression." Chiropractors are not to have the right to practice surgery or obstetrics, to prescribe drugs or to administer anesthetics.

IOWA

Tuberculin Testing of Cattle to Be Resumed — Renewed enforcement of the state law for the tuberculin testing of cattle will be carried out in full, beginning March 15. Secretary of Agriculture Murray suspended the testing, February 1, pending action on the Foster bill by the forty-fifth annual assembly of the state of Iowa. The announcement to renew enforcement followed the defeat of the bill by a vote of 80 to 24. Provisions of the bill made tuberculin testing of cattle in Iowa optional rather than mandatory. Since tuberculin testing began in Iowa, 9,963,707 tuberculin tests have been

applied and 207,463 reactors removed, 21,679 of which had generalized cases of tuberculosis. Only 12 per cent of the reactors failed to show visible lesions, from 65 to 70 per cent of them coming from herds in which they were associated with other animals which did show visible lesions. Of the ninety-nine counties in Iowa, seventy-five are already accredited.

Society News—Dr Herbert W. Rathe addressed the Bremer County Medical Society in Waverly, Dec. 14, 1932, on treatment of cardiac failure. At a meeting of the Cerro Gordo County Medical Society in Mason City, Dec. 20, 1932, Dr. Paul A. O'Leary, Rochester, Minn., spoke on general therapeutic problems of syphilis. Drs. Guy P. Reed, Davis City, and Jesse S. Coontz, Leon, addressed the Decatur County Medical Society, Dec. 9, 1932, on basal metabolism and acute infectious diseases, respectively. Speakers before the Page County Medical Society in Shenandoah, Dec. 1, 1932, were Drs. Herbert H. Davis and George P. Pratt, both of Omaha, on "Significance of a Lump in the Breast" and "Pneumonia and Upper Respiratory Infections," respectively. A meeting of the Four County Medical Society (Buena Vista, Cherokee, Ida and Plymouth counties) in Cherokee, Dec. 13, 1932, was addressed, among others, by Dr. Harold E. Farnsworth, Storm Lake, on "Acute Lymphatic Leukemia in Infancy." Dr. Park A. Findley, Des Moines, formerly sheriff of Polk County, has been selected chief of the Iowa State Bureau of Criminal Investigation. Dr. Ernest Kelley, Omaha, addressed the Black Hawk County Medical Society, Waterloo, January 17, on "Multiple Sclerosis and Cerebellar Abscess." Dr. Harold M. Hays, New York, addressed the Linn County Medical Society, March 9, on "Preventive and Alleviating Methods in Treatment of Deafness." Dr. Benjamin L. Knight, Cedar Rapids, gave a paper on "The Gallbladder in Office Practice."

KANSAS

Bills Introduced—H. 728 proposes to permit osteopaths, chiropractors, dentists, chiropodists and optometrists to use the prefix "doctor," provided they add after their names the proper designation of their school of practice. H. 740 proposes to permit all licensed physicians, osteopaths or chiropractors to practice within the confines of any hospital exempt from taxation.

LOUISIANA

Personal—Dr. Lionel L. Cazenavette, who has been in charge of the clinic for nervous diseases at Charity Hospital since November, 1897, was recently appointed superintendent of the City Hospital for Mental Diseases.

Medical School Approved—At the business meeting of the Council on Medical Education and Hospitals of the American Medical Association in Chicago, February 12, the Louisiana State University Medical Center was approved for class A rating. Dr. Arthur Vidrine, superintendent of Charity Hospital, is dean of the school, which was established in 1931.

Dr. Kostmayer Appointed Acting Dean—Dr. Hiram W. Kostmayer, professor and head of the department of gynecology, Tulane University Graduate School of Medicine, New Orleans, has been appointed acting dean of the school, succeeding the late Dr. Henry Daspit, it is reported. Dr. Kostmayer was president of the Orleans Parish Medical Society in 1923.

Society News—At a joint meeting of the New Orleans Gastro-Enterological Society and the Hotel Dieu staff, Dec. 22, 1932, Drs. Donovan C. Browne spoke on "Treatment of Peptic Ulcers with Nonspecific Protein Observations After One Year," Charles W. Duval, "Hepatic Changes in Certain Cases of Jaundice," and Ruth G. Aleman, "Postoperative Treatment of Ruptured Appendix in Children." Dr. Henry W. E. Walther, New Orleans, addressed the students of Louisiana State University in Baton Rouge, January 11, on "Prevention of Syphilis: A Problem for the Youth of the Land." At a meeting of the Orleans Parish Medical Society, New Orleans, January 23, Dr. James L. Nix, Jr., spoke on "European hospitals and clinics," and Dr. Allan C. Eustis, thyroid disease.

MAINE

Bill Introduced—H. 1467 proposes to authorize the board of registration of medicine together with one podiatrist to examine and license persons to practice podiatry. Podiatry is defined as the external treatment of the structure of the human foot by medical, mechanical or surgical means without the use of anaesthetics other than such local anaesthetics as are recognized to have no immediate cumulative, poisonous, harmful or systematic action.

MARYLAND

Personal—Dr. Christian Deetjen presented to the Medical and Chirurgical Faculty of Maryland his collection of x-ray tubes, January 17, at a meeting of the Osler Historical Society. According to the bulletin of the faculty, almost from the beginning of his work Dr. Deetjen had preserved the tubes that he discarded so that this collection shows graphically the development of the science and in years to come will be a valuable exhibit.

Society News—The Society of Hygiene was addressed at the School of Hygiene and Public Health, Johns Hopkins University, January 18, by Dr. Harry S. Mustard on "The Eastern Health District: A Field for Studies in Public Health Problems and Methods," and Marvin M. Harris, Ph.D., and Dr. Linda B. Lange on "Preservation of Acid-Fast Bacteria in Vacuo." A symposium on hermaphroditism was presented before the Medical and Chirurgical Faculty of Maryland, February 17, by Herbert S. Jennings, LL.D., Hugh H. Young and George L. Streeter, Baltimore.

Infant Mortality Rate—With a rate of 68.4 per thousand live births, the infant mortality rate in 1932 was the lowest ever recorded in Maryland, according to the state department of health. New low rates per hundred thousand of population were also noted for typhoid (3), diphtheria (3.1) and tuberculosis (90.2). There were 134 maternal deaths in 1932, as compared with 180 in 1931. No maternal deaths were reported in Calvert, Carroll, Howard, Kent, Prince George's and Queen Anne's counties. There were 42,621 cases of communicable disease, as compared with 66,284 in 1931.

Bills Introduced—H. 230, to amend the chiropody practice act, proposes that the board of medical examiners of the Medical and Chirurgical Faculty of Maryland select the board of chiropody examiners, three of whose members must be members of the Maryland Podiatric Association and one, a member of the board of medical examiners of the Medical and Chirurgical Faculty of Maryland. H. 249, to amend the dental practice act, proposes (1) to authorize the board of dental examiners to grant limited registration to individuals to practice dentistry within the confines of a designated hospital, (2) to authorize the board to revoke the licenses of those licensees who indulge in specified kinds of advertising, (3) to redefine the practice of dentistry so as apparently to limit the right of a corporation to practice and (4) that licensees actually in practice be exempt from jury service.

MASSACHUSETTS

Appointments at Harvard—The *New England Journal of Medicine* notes the following recent faculty appointments, among others, at Harvard University Medical School:

Dr. George Kenneth Mallory, instructor in pathology.
Dr. Robert Alexander Gregory, assistant in neurology.
Danella Straup-Cope, Ph.D., research fellow in physical chemistry.
Clifford Ladd Prosser, Ph.D., research fellow in physiology.
Dr. Wyman Whittemore, associate in surgery, Courses for Graduates.
Dr. Charles Hazard Kimberly, research fellow in psychiatry.
Dr. Dudley Merrill, assistant in medicine.
Dr. Theodore Cary Pratt, assistant in surgery, Courses for Graduates.
Dr. John D. Stewart, assistant in surgery.

Cutter Lectures—Louis I. Dublin, Ph.D., third vice president and statistician, Metropolitan Life Insurance Company, New York, will deliver the Cutter Lectures on Preventive Medicine at Harvard University Medical School, Boston. Dr. Dublin's subject will be "Trends in Longevity, Past, Present and Future," and the dates for the lectures will be March 17 and March 20. These lectures are given annually under the terms of a bequest from John Clarence Cutter, whose will provided that the lectures so given should be styled the Cutter Lectures on Preventive Medicine and that they should be delivered in Boston, free to the medical profession and the press.

Dr. Mallory Retires—Dr. Frank Burr Mallory, chief of the department of pathology at Boston City Hospital, recently retired from service with that institution, having reached the age limit of 70. Dr. Mallory has been connected with the hospital since 1891 and chief of the pathologic department for several years. In 1890 he became associated with Harvard University Medical School, his alma mater, as assistant in histology and has since held several teaching positions, becoming professor of pathology in 1928. Dr. Mallory is the author of books on pathology and contributions to medical journals. He has been editor of the *American Journal of Pathology* since 1925. Resolutions of appreciation for Dr. Mallory's service were adopted by officials of Boston City Hospital. It was stated that he will continue as consultant to the hospital, working without remuneration. Dr. Mallory is the father of

Drs Tracy B and George Kenneth Mallory both pathologists in Boston

Society News—A symposium on psychiatry was presented before a joint meeting of the Boston Medical Library and the Suffolk District Medical Society, January 25, by Drs Ralph A Noble, Sydney, Australia, at present with the National Committee for Mental Hygiene, New York, Donald J MacPherson and Arlie V Bock.—Dr Eric P Stone, Providence, R I, addressed the Harvard Medical Society, January 10, on "Medical Practices of the Aboriginal Americans".—The Middlesex East District Medical Society, at a meeting in Wakefield, January 11, heard Dr Wilson G Smilie, Boston, discuss respiratory infections.—Dr Harvey W Van Allen, Springfield, spoke on "Lung Cavities—Their Control a Necessity to Arrest of the Disease, Treatment by Various Methods" before the Franklin District Medical Society in Greenfield, January 10.—The New England Heart Association held a special meeting, January 11, to discuss the social problem of the child with heart disease.—Dr Albert Warren Stearns, dean, Tufts College Medical School, addressed the William Harvey Society of the school, February 20 on "Conduct as a Medical Problem". Dr Lawrason Brown Saranac Lake, N Y, gave an address, February 10, on "Boston's Contribution to Our Knowledge of Tuberculosis".—Dr Morris Fishbein, Chicago, gave one of a course of lectures sponsored by the extension division of the Massachusetts Department of Education, February 23, on "Changes in the World of Medicine". Dr Richard C Cabot, Boston, will speak, March 23, on "Changes in Ethical Standards".

MICHIGAN

Typhoid at Low Level—Fifty-seven cases of typhoid with eight deaths were reported in Detroit during 1932, a new low level for the disease. The source of infection was definitely traced in thirty-three cases, the probable source was found in eleven, while in thirteen it was unknown. Of the known sources, twenty-five were outside Detroit and eight were found to be within the city. Of those in Detroit, three were traced directly to typhoid carriers. Three cases occurred as a result of swimming in water known to be polluted, and two were the result of direct infection from contact with cases already existing in homes. Thirty-six patients were hospitalized.

Appointments to Kellogg Foundation—Dr Garner M Byington, Charlotte, has been appointed associate medical director of the W K Kellogg Foundation, Battle Creek, a newly created executive position. Dr Byington, who was to assume his duties March 1 will have charge of all medical care for the foundation with headquarters in Battle Creek. His practice, which for the last eight years has been limited to the study of children's diseases, will be taken over by Dr Clinton J Severer, Mulliken. Dr Joseph W Davis took up his duties as director of the newly established health unit in Eaton County, February 1. For the past year he has been director of a mobile unit of the West Virginia Department of Health. Previously he was engaged in public health work in Kentucky.

MINNESOTA

Bills Introduced—H 999, to amend the chiropractic practice act, proposes that licentiates shall not be granted annual renewals of their licenses unless they present evidence that in the preceding year they attended at least one of the two-day educational programs conducted by the Minnesota Chiropractic Association. H 1002, to amend the chiropractic practice act, proposes, in effect, to permit applicants for licenses to practice chiropractic to be licensed without being examined by the state board of examiners in the basic sciences. H 919 proposes to make it unlawful for any publicly owned state hospital to refuse medical treatment to any applicant who has been injured in an industrial accident.

MISSISSIPPI

Hookworm Survey—The examinations in eight counties in the state have been completed in a hookworm survey carried on by the Mississippi State Board of Health in cooperation with the department of preventive medicine, Vanderbilt University School of Medicine, and the International Health Division of the Rockefeller Foundation. The survey was begun Sept 1, 1932. Twenty per cent of the 8,363 specimens examined showed the presence of hookworm ova. Of those found positive, there was an average of 135 worms per person. Thus far, the results of the survey indicate that intensive parasites are a problem of only the white race, the report stated. Negroes showed less than 2 per cent positive for hookworm ova.

NEBRASKA

Society News—Dr Sydnor D Maiden, Council Bluffs, Iowa, among others, addressed the Omaha-Douglas County Medical Society, Omaha, February 14, on "Bronchoscopy and Esophagoscopy from the Standpoint of General Medicine".—Drs Olin J Cameron and Charles C Tomlinson, Omaha, addressed the Nebraska Pediatric Society, Omaha, January 12, on acrodynia.—Omaha physicians recently organized the Omaha Mid-West Clinical Society to sponsor an annual graduate medical assembly. Officers of the society, whose membership is limited to 100, are Drs Byron B Davis, president, Adolph Sachs, vice president, Joseph D McCarthy, secretary and director of clinics, and William P Wherry, comptroller.

NEW JERSEY

Bill Introduced—S 229 proposes to repeal the laws regulating the possession and distribution of narcotics and to enact the uniform narcotic practice act.

NEW MEXICO

Bill Introduced—H 170 proposes to create a board of registration in chiropody and to regulate the practice of chiropody. "A chiropodist is defined as one who examines, diagnoses, prescribes shoes and orthopedic appliances necessary in said practice (of chiropody) who treats medically, mechanically or surgically the ailments of the human foot and limb, and massage in connection therewith, except the amputation of the toes or foot, or the use of anesthetic other than local."

NEW YORK

Changes in Hospital Superintendents—Dr George A Smith, superintendent of Central Islip State Hospital, has retired because of the statutory age limit, and Dr David Corcoran, formerly first assistant physician at the Brooklyn State Hospital, Queens Village, has been appointed to succeed him. Dr Charles S Parker was appointed superintendent of Kings Park State Hospital, January 1, to succeed Dr William J Tiffany, who is now superintendent of Pilgrim State Hospital. Dr Parker had been acting superintendent since November, 1931.

Society News—At the January meeting of the Medical Society of the County of Albany, speakers were Drs James S Lyons, on prostatic hypertrophy, Arthur W Wright, demonstration of pathologic prostate glands, and James N Vander Veer, anomalies of the kidneys and ureters as shown by intravenous urography.—The Columbia County board of supervisors recently voted to establish a county health department to include the town of Hudson. Half the cost of maintenance will be paid by the state.—The New York State Pharmaceutical Association at a meeting in New York, January 9, adopted a resolution opposing the majority report of the Committee on the Costs of Medical Care as detrimental to the best interests of pharmacists and the public.

Bills Introduced—A 1424 proposes to repeal the laws regulating the possession and distribution of narcotic drugs and to enact the uniform narcotic drug act. A 1526 and S 1343, to amend the laws relating to the practice of osteopathy, propose (1) to denominate osteopaths as osteopathic physicians and (2) to eliminate the provisions prohibiting osteopaths from administering drugs or performing surgery with the use of instruments, substituting for the eliminated matter the following: "A license to practice osteopathy shall not entitle the holder thereof to perform any surgical operation involving incision for the opening of a natural body cavity, for the removal of cancer or other tumor, for the amputation of an extremity or an appendage, or for the removal of any gland or organ, or part thereof, of the human body, nor shall such license permit the holder thereof to administer drugs, except narcotics, anesthetics, antiseptics, serums, vaccines and antitoxins."

New York City

Dr Park Appointed to New Professorship—Dr William H Park, director of laboratories, New York City Department of Health, has been appointed the first Hermann M Biggs professor of preventive medicine at New York University and Bellevue Hospital. He has been professor of bacteriology and hygiene at the school since 1897. The new professorship was established by a memorial fund begun soon after the death of Dr Biggs in 1923 and recently completed by a bequest from his widow and gifts from his son and daughter and from the Milbank Memorial Fund. Dr Park was for many years associated with Dr Biggs in the health department during the latter's long service as director of the diagnostic laboratory and later as city health officer.

Society News—The New York Institute of Clinical Oral Pathology was recently organized with a membership of 100 physicians and dentists. It is planned to extend its activities over the country. Advisers of the institute are said to include Drs James Ewing, Harlow Brooks, George H Semken and Abraham Flexner. A symposium on psychiatry was presented at the meeting of the International and Spanish-Speaking Association of Physicians, Dentists and Pharmacists, February 17, by Drs Adolf Meyer, Baltimore, Ricardo Sarmiento Laspiur, Buenos Aires, Foster Kennedy, Bernard Glueck and Clarence P Oberndorf. Dr Joseph Samuel Stovin, among others, addressed the New York Physical Therapy Society, February 1, on "Physical Measures in the Treatment of Atrophic Rhinitis." Dr Mills Sturtevant addressed the Medical Society of the County of Queens, February 17, on peptic ulcer. The section on genito-urinary surgery of the New York Academy of Medicine met, February 15, at New York Hospital, where a clinic was given by the department of urology James Buchanan Brady Foundation, under the direction of Dr Oswald S Lowsley.

OHIO

Dr Doull to Study Leprosy—Dr James Angus Doull, professor of hygiene and public health, Western Reserve University School of Medicine, Cleveland, will sail, March 25, for the Philippine Islands to organize an epidemiologic study of leprosy under the auspices of the Leonard Wood Memorial for the Eradication of Leprosy. Dr Doull will remain in the islands, principally at Cebu, about six months to organize the studies which will be continued for several years. Among other factors to be studied is the frequency of leprosy in relation to diet, age, living conditions and known contact with previous cases.

Dr Haines Honored—Dr Willard D Haines, Cincinnati, was the guest of honor at a testimonial dinner given by medical and other friends February 15, marking his completion of fifty years of practice. Dr George W Crile, Cleveland, was the principal speaker and Dr Robert Carothers was toastmaster. Dr Haines was graduated in 1884 from the old Medical College of Ohio, Cincinnati, now the University of Cincinnati College of Medicine. For many years he has been associate professor of clinical surgery at the medical school and a staff surgeon of the Cincinnati General Hospital. Others who paid tribute to the physician were Drs Martin H Fischer, Edwin Khoun and Edwin W Mitchell, Mayor Russell Wilson, Attorney James A Stewart, representing the Cincinnati bar, and Judge Thomas H Darby.

OKLAHOMA

Bill Introduced—S 275 to amend the law authorizing the sexual sterilization of certain socially inadequate inmates of state institutions proposes to authorize the sterilization also of any inmate of a penal institution who has been convicted of felony three times.

Society News—Dr Frank H McGregor Mangum, addressed the Pottawatomie County Medical Society Shawnee, in January, on diagnosis and surgery of the gallbladder. Drs Henry T Turner Oklahoma City, and McLain Rogers, Clinton, addressed the Western Oklahoma Medical Society, Dec 20, 1932 at Clinton on endocrinology and injuries to the head respectively. Drs James Stevenson and Pleasant P Nesbitt, Tulsa addressed the Muskogee County Medical Society, Muskogee January 9 on eczema and empyema respectively. Dr Louis Rudolph Chicago Robert J Crossen St Louis and James R Reinberger Memphis Tenn delivered lectures on obstetrics and gynecology in Muskogee Dec 7 1932 under the auspices of the extension division of the University of Oklahoma. Dr Julius W Neweg Duncan was named president elect of the Southern Oklahoma Medical Association at the annual meeting at Ardmore in December. Dr Berry H Burnett Duncan was elected secretary. This society is made up of physicians of seventeen counties of southern Oklahoma. Dr Roger Q Archibald addressed the Tulsa County Medical Society February 13 at a meeting at Morningstar Hospital Tulsa on "Bilateral Pneumothorax." Dr Wade Slicker held an orthopedic clinic and Dr James C Peden presented a case of acute pneumothorax in diffuse tuberculosis.

OREGON

Internship Required for a License—Dr Joseph F Wood Portland has been elected secretary of the Board of Medical Examiners of the State of Oregon to succeed the late Dr Clarence I McCusker. The board announces that medical students graduating in 1933 and thereafter will not receive a license to practice medicine in Oregon until they have com-

pleted a year's internship, certified by the board of an accredited hospital.

Society News—Dr Charles H Manlove, Portland, addressed the Oregon Pathological Society, Portland, January 9, on "The Basis of Biopsy." Dr Albert M Webster, Portland, addressed the Polk-Yamhill-Marion Counties Medical Society, Salem, January 10, on "Medical Services and the Public." George E. Burget, Ph D, Portland, addressed the Portland Academy of Medicine January 12, on "Use of the Closed Intestinal Loop for the Study of Some Problems in Physiology."

University News—The annual meeting of alumni of the University of Oregon Medical School was held in Portland, March 6-8, with Dr Frank W Lynch, San Francisco, as guest speaker. Clinics were held each morning and lecture programs in the afternoons and evenings. Arthur R Moore, Ph D, professor of general physiology at the University of Oregon Medical School, will leave shortly to spend fifteen months as visiting professor at Tohoku Imperial University, Sendai, Japan, under the auspices of the Rockefeller Foundation. He will lecture in the graduate school on experimental embryology and physiology of the nervous system.

PENNSYLVANIA

Personal—Governor Pinchot has appointed Dr Samuel McC Hamill, Philadelphia, chairman of an emergency child health committee to supplement the work of relief organizations, with special emphasis on nutrition.

Philadelphia

Seminars on Pneumonia—The third series of graduate seminars sponsored by the Philadelphia County Medical Society is concerned with pneumonia. Dr Arthur C Morgan gave the introductory lecture, February 17, and the following schedule was announced for the series:

February 24 Drs Baldwin Lucke pathology and John A Kolmer, immunity and serum therapy
March 3 Drs Mitchell Bernstein etiology and Samuel A Loewen berg clinical manifestations
March 10 Drs Edward Weiss, cardiac and renal complications and Herbert T Kelly metabolism and diet
March 17 Drs Harry Lowenburg pneumonia in children and Henry D Jump treatment of pneumonia

Society News—Dr Charles W Burr addressed the Philadelphia Neurological Society, February 24, on "Heredity in St. Vitus' Dance." A symposium on backache was presented before the Northern Medical Association of Philadelphia, February 20, with the following speakers: Drs Joseph Bank, John B Lownes, Alfred Gordon, Frederick Hurst Maier and Harry Hudson. The Philadelphia County Medical Society held a "Proctologic Night," February 22 with the following speakers: Drs Descum C McKenney, Buffalo "Clinical Significance of Bleeding from the Colon, Rectum and Anus", Collier F Martin "Some Popular Fallacies Concerning Anorectal Diseases," and Harry Z Hilsman, "Operable Anomalies of the Anus and Rectum." The society sponsored a group of seminars on maternal mortality in eight Philadelphia hospitals, February 16.

TEXAS

Bills Introduced—H 627 proposes to make it unlawful for any pharmacy to distribute at retail or wholesale tobacco, foods, hardware, jewelry and all other articles except drugs or medicines having a therapeutic value. H 605, to amend the dental practice act, proposes, in effect, to prohibit the operation of chain dental offices.

Clinical Conference at Dallas—The Fifth Annual Clinical Conference of the Dallas Southern Clinical Society will be held March 27-31. General assemblies will be held each morning with the following guest speakers:

Dr Cyrus C Sturgis Ann Arbor Mich Diet Digitalis and Diuretics in Treatment of Congestive Heart Failure
Dr Charles C Dennis Kansas City Mo Role of Malaria in Treatment of Syphilis
Dr Joseph F McCarthy New York Present Status of Surgical Therapy of the Senile Prostate
Dr Jewell F Barker Baltimore Advances in Endocrine Diagnosis and Treatment
Dr Philip H Kreuscher Chicago Backache
Dr Arthur E Hertzler Kansas City Differential Diagnosis of Upper Abdominal Conditions
Dr Percival Bailey Chicago Importance of Pathologic Classifications in Diagnosis and Treatment of Brain Tumors
Dr Harry S Crossen St. Louis Prevention of Cancer of the Uterus
Dr Eugene R Lewis Los Angeles Physical and Chemical Aspects of Local Tissue Changes
Dr Joseph Brearemann Chicago The Acute Abdomen in the Child
Dr Louis A Bue Rochester Minn. Problems in Proctology for the General Practitioner

Four evening symposiums will be presented led by Dallas physicians: Dr Henry M Winans on the anemias, John O

McReynolds, on sinus diseases. Charles M. Rosser, abdominal uterine bleeding, and Hugh Leslie Moore, digestion in the infant. Dr. Edward H. Cary, Dallas, President, American Medical Association, will address a public meeting, Monday evening, on the work of the Association and Dr. Barker will give an address entitled "On Growing Old." In addition, there will be clinics each afternoon at Baylor, St. Paul, Parkland, and Dallas Methodist hospitals, round table luncheons at which the guest speakers will make short talks and answer questions, and graduate lectures by Dallas physicians each morning after Monday.

UTAH

Annual Registration Due April 1—All practitioners of medicine and surgery holding licenses in Utah are required to register annually on or before April 1, with the Department of Registration, and to pay a fee of \$3. If a licensee neglects to reregister within from ninety days to six months after April 1, his license can be revoked and will be reinstated thereafter only on his paying the delinquent registration fees and an additional year's fee as a penalty.

WASHINGTON

Bills Introduced—S. 294 proposes to prohibit any hospital exempt from taxation from denying to any physician licensed to practice medicine and surgery in the state the right to practice within the confines of the hospital on an equal basis with all other licensed physicians and surgeons. H. 408 proposes to authorize the boards of commissioners of the various counties to form local health districts to be administered by district health officers. S. 348 proposes to create a state department of maternal and child welfare and to establish clinics in Olympia, Seattle and Spokane. All physicians are to be permitted to prescribe contraceptives for their patients, but they must report to the department the facts of individual cases. S. 328, to amend the workmen's compensation act, proposes, among other things that compensation for industrial hernias be allowed only on proof that there was an injury caused by accident that the hernia appeared suddenly, that it was accompanied by pain, that the hernia immediately followed the accident, that the hernia did not exist prior to the accident, and that the facts were reported to the employer within forty-eight hours next following the occurrence of the hernia. S. 308 proposes to transfer from the director of licenses to the several professional examining committees the right to pass on the qualifications of applicants to determine their fitness for examination, and the duty of conducting proceedings to revoke licenses to practice and of enforcing all laws relating to their respective branches of the healing art. It proposes to authorize such committees to make such rules and regulations as they deem necessary to the discharge of their duties.

WEST VIRGINIA

Bill Introduced—S. 108, to supplement the pharmacy practice act, proposes (1) to require the annual registration of pharmacies, (2) to make it the duty of county prosecuting attorneys to whom the board of pharmacy shall report any violations of the act to cause appropriate proceedings to be commenced and prosecuted, and (3) to require all pharmacies to have on file the latest decennial edition of the United States Pharmacopeia and of the National Formulary.

WISCONSIN

Bills Introduced—A. 403 proposes to repeal the law requiring applicants for marriage licenses to present medical certificates as to freedom from venereal disease. A. 455, to amend the workmen's compensation act, proposes, in effect, to make compensable all occupational diseases arising out of employments covered by the act. A. 459 proposes to require physicians to report to the state board of health the names of patients having cancer, carcinoma, sarcoma or other malignant growths.

Society News—At a meeting of the Sheboygan County Medical Society, Sheboygan, Dec. 15, 1932, Drs. Silvanus A. Morton and Arthur A. Pleyte, Milwaukee, presented papers on radiologic diagnosis of diseases of the chest.—The Waukesha County Medical Society at a meeting, Dec. 7, 1932, endorsed the action of the American Medical Association with respect to its attitude toward the minority report of the Committee on the Costs of Medical Care.—Drs. Ralph Pemberton, Philadelphia, and Robert B. Osgood, Boston, addressed the Milwaukee County Medical Society, Milwaukee, January 19, on arthritis.—Dr. Karl E. Kassowitz has been elected president of the Milwaukee Pediatric Society.

WYOMING

Annual Registration Due April 1—All practitioners of medicine and surgery licensed to practice in Wyoming are required by law to register on or before April 1, with the secretary of the Board of Medical Examiners, and to pay a fee of \$2.50. If a licensee fails to pay the fee within three months after April 1, his license can be annulled, and if annulled it will be restored to him only on his paying the stated fee, plus \$5 as a penalty.

GENERAL

Pan-American Medical Congress—The fourth congress of the Pan-American Medical Association will be held in Dallas, Texas, March 21-25. Dr. Francisco M. Fernandez, Havana, Cuba, is president of the Association, and Dr. John O. McReynolds, Dallas, is president of the congress. A formal inaugural session will be held Tuesday evening, March 21, at which foreign delegates will be presented. Group breakfasts and luncheons have been arranged each day at the Adolphus Hotel for the sections concerned with surgery and at the Baker Hotel for the medical group. Regular sessions will also be held at these hotels. The congress is divided into thirteen sections, each with presidents from the United States and a Spanish-speaking country.

Medical Bills In Congress—S. J. Res. 262 was passed by the Senate and House, authorizing the joint congressional committee investigating veterans' legislation to continue its activities after March 4, 1933, and until 60 days after the first meeting day of the Seventy-Third Congress. H. R. 14395, relating to the prescribing of medicinal liquor, failed to pass. After its passage by the House, this bill was favorably reported by the Senate Committee on the Judiciary and was placed on the Senate calendar. The Senate was prevented from considering the bill by the threat of a filibuster by Senator Brookhart—a "lame duck" senator from Iowa—that would prevent the transaction of any business whatever during the remaining hours of the session.

Field Service in Nursing—Field service will be one of the major activities of the department of studies of the National League of Nursing Education during the coming year, according to a recent announcement. The new service, to be available to any state or institution desiring to have a study made, will undertake studies relating to a particular phase of the nursing service or to the activity as a whole. There will be no fixed charge; each study will be considered separately and, so far as the league is able, it will endeavor to make the costs meet the available resources of the state or the institution requesting the study. The league believes, it was stated, that the most important service it can render to the hospital, to the community and to nursing is field service, since it cannot send out patterns from headquarters to fit all states or institutions because of local differences in tradition, financial resources and ways of thinking.

Bequests and Donations—The following bequests and donations were recently announced:

Home for Destitute Crippled Children, \$20,000, and the Illinois Children's Home and Aid Society, \$10,000, both of Chicago, by the will of Donald M. Ryerson.

Mr. and Mrs. Guy W. Everett recently gave a \$10,000 trust fund to the city of Waseca, Minn., for a hospital.

Mount Vernon Hospital at Mount Vernon, New York, \$20,000, and a residuary fund of \$100,000 by the will of the late Mrs. Frances M. Willson.

Lincoln Hospital, New York, \$10,000, under the will of the late Flora Elshah Isham.

St. Luke's Hospital, \$10,000, and Home for Destitute Crippled Children and the Illinois Society for Prevention of Blindness, \$2,000 each, all of Chicago, to be paid when other bequests are settled, by the will of the late John Crerar.

Augustana Hospital, Chicago, the major portion of the \$40,000 estate of the late Jefferson D. Wright.

Misericordia, Saint Agnes, Jefferson Presbyterian and Hahnemann hospitals, Philadelphia, will receive \$10,000 each from the estate of the late James H. Billington on the death of his wife.

Jewish Hospital, Philadelphia, \$5,000, under the will of the late Ferdinand Rosenberg.

Presbyterian, University and Woman's hospitals, Philadelphia, \$5,000 each under the will of the late Margaret Dornan.

Mount Sinai Hospital, New York, \$20,000 held in trust from the will of Mrs. Esther Wallach Dryfoos.

Children's Orthopedic Hospital, Seattle, Wash., \$5,000 under the will of Mrs. Minnie W. Schalkenbach.

Montefiore Hospital for Chronic Diseases, New York, New York Association for the Blind Hospital for Ruptured and Crippled New York Babies' Hospital of the City of New York, Hebrew Orphan Asylum of New York, Cedars of Lebanon Hospital, Los Angeles, Calif., each \$9,000 by the will of Mrs. Carrie Guggenheim.

Association for Improving the Condition of the Poor, New York, \$10,000, and Stuyvesant Square Hospital, \$7,500, by the will of Abraham Erlanger.

Society News—At the annual meeting of the Federation of State Medical Boards of the United States in Chicago, February 13-14, Dr. Henry M. Fitzhugh, Westminster, Md., was

named president-elect Dr George M Williamson, Grand Forks, N D, became president, Dr James N Baker, Montgomery, Ala, vice president, and Dr Walter L Bierring, Des Moines, Iowa, was reelected secretary Dr William D Cutter, secretary, Council on Medical Education and Hospitals, American Medical Association, Chicago, was appointed managing editor of the *Federation Bulletin* to succeed Dr Nathan P Colwell, who asked to be relieved of that position—The next meeting of the Harvey Cushing Society will be held at the clinic of Dr Roy Glenwood Spurling, Louisville, Ky, April 13-14 Dr William P Van Wagenen, Rochester, N Y, is the president of the society, organized last year Active members engage in investigation in neurology, neurosurgery and allied subjects Dr Tracy J Putnam, Boston, is secretary—Dr John C Meakins, professor of medicine, McGill University Faculty of Medicine, Montreal, was chosen president-elect of the American College of Physicians at the annual session in Montreal, February 6-10 Dr George M Piersol, Philadelphia, was installed as president The 1934 session will be held in Chicago—The American Public Health Association will hold its sixty-second annual meeting in Indianapolis, October 9-12

CANADA

Personal—The George Armstrong Peters Prize of the University of Toronto has been awarded to Dr William S Keith, of the staff of the Hospital for Sick Children, in recognition of his work in the surgical treatment of broken bones and bone grafts

Hospital News—The Mara Memorial Laboratory for research on tuberculosis was recently opened at Queen Alexandra Sanatorium, London, Ont, with ceremonies at which Dr John G Fitzgerald, dean University of Toronto Faculty of Medicine, made the principal address The laboratory is the gift of Mr Wilfred Mara, London, in memory of his family

Society News—Dr Edmund B Piper, Philadelphia, addressed the Toronto Academy of Medicine, Dec. 6, 1932, on "Management of Complications of Late Pregnancy and Labor"—Dr Egerton L Pope, professor of medicine, University of Alberta Faculty of Medicine, Edmonton, delivered the annual Gordon Bell Memorial Lecture under the auspices of the Winnipeg Medical Society at the University of Manitoba, Dec 5, 1932 His subject was "Emotion and Reason"

Cancer Institute—The provincial government of Ontario in cooperation with Queen's University Kingston has arranged to establish a cancer institute or clinic at the Kingston General Hospital according to a report of the American consul at Kingston to the U S Department of State The hospital will provide space for treatment of twenty resident cases Modern x ray equipment is being purchased and the government is to furnish radium sufficient to meet the needs of the institute A supervisory committee representing the province the university and the hospital is to be appointed and a diagnostic committee composed of members of the hospital staff is in process of formation The new institute which is expected to be in operation by April is one of three to be established in Ontario in accordance with recommendations of a special cancer commission published in March, 1932

LATIN AMERICA

Antiplague Campaign in Peru—Surgeon Clifford R Eskey of the U S Public Health Service in a recent issue of *Public Health Reports* describes an epidemiologic survey of plague in Peru carried out under the direction of Medical Director John D Long also of the service Active antiplague measures were instituted in Lima and Callao in November, 1930 and in other provinces during the following December and January Assistants were stationed in all the principal ports to supervise trapping and poisoning of rats and to inoculate guinea-pigs with material from the rats caught each day to determine the presence of infection In Lima more than 25,000 rats were caught More than 70 tons of poison was distributed to 100 towns and the adjacent haciendas From January to June 1931 only ninety-seven cases in human beings were reported the smallest number ever recorded in a similar period In the city of Lima no cases were reported from March 15 to June 15 It was believed that the antiplague measures had been responsible for the reduction though the investigators emphasized the statement that the time elapsed was too short to judge the permanence of the results They had special emphasis on rat proof construction of buildings as it was shown definitely that the incidence of plague was related in the communities in which rat harborage was present

A National Medical Service

When the socialist government was in office, a demand arose among its followers for a complete state medical service for every one The danger of something of the kind led the British Medical Association to formulate a scheme with a view to preserving some of the individualism of the profession With the defeat of the socialist government the danger of such a sudden transformation passed, but not the danger of further socialization or medical service The national health insurance scheme does not provide medical attendance for the wives and children of the insured or any consultant, specialist or hospital service, and it is only the financial difficulty that has prevented extension in these directions The further socialization of the medical profession remains a political question which exercises the British Medical Association more than any other problem

An address, delivered before the Brighton division of the association by Sir Henry Brackenbury, chairman of the council, on "The Essentials of a National Medical Service" summarizes the policy of the association He laid down four essential features for a national medical service 1 It must offer scope and opportunity for the threefold aim of modern medicine—curative, preventive and constructive 2 It should afford opportunities for clinical and laboratory research 3 It should provide a physician for every individual, as in private practice Sir Henry protested against any assumption that the general practitioner represented an inferior branch of the profession The relation between physician and patient was based on two things—it was a relation between physician and patient primarily, if not solely, with no one else intervening, and it was a free relation The physician was not confined to some limited system within which he must treat his patient, and there was a free choice both of patient by physician and especially of physician by patient 4 The service must be a complete one, providing not only the general practitioner but also the consultant and specialist, the various ancillary services and the necessary institutional accommodation Should the service be provided for everybody, regardless of social status? The medical profession was in favor of providing a national service only for those who could not provide it for themselves This view was not determined by monetary considerations but by its jealousy for preserving the fundamental relations of physician and patient as set out before, which were completely preserved in private practice With regard to administration, he advocated unification of the health services of the country, so as to bring the insurance service into close relation with public health and poor law administration

Institutional provision could not be provided in exactly the same way by a compulsory insurance system, but it was necessary for a complete service With the tendency of hospitals to shift from the purely charitable basis to one more or less contributory the medical staff should be recognized financially in some form or other Another essential was the admission of the general practitioner with responsibility for his own patients, under hospital conditions Physicians should be brought into close relation with the public health service and in fact be considered an integral part of it Finally there was the relation of the physician with other persons of the health service—midwives school nurses and health visitors These should not be regarded merely as subordinates of the health officer but as helpers to all physicians of the area

Sterilization of the Unfit

Sir Henry Brackenbury addressed another meeting of the division on "Sterilization of the Unfit in Its Relation to Private Medical Practice and to Certification." He referred to the government committee now considering the subject of hereditary transmission of mental defect. Sooner or later the profession would be faced with the duty of saying that a case was one of mental deficiency in order that some communal action might be taken or that, with due precautions, there should be an operation for sterilization. An expert mental deficiency committee of the British Medical Association expressed the view that sterilization even widely applied to mental defectives, would cause no appreciable difference in the number of such defectives, at least for many generations. Although it might be easy to certify that an individual was a mental defective, the more formidable difficulty remained of saying whether the mental deficiency was hereditary and would be handed on by the individual. If that could not be said sterilization was futile. Any trait whether physical or mental was not, strictly speaking, hereditary or environmental, it was the end-result of both hereditary and environmental causes acting on one another, and it must be extremely difficult to disentangle what was hereditary from what was not and to say that for the sake of the race a person ought to be sterilized. He would have no hesitation in advising the sterilization of mental defectives on racial grounds if it was known that the production of others would be prevented, but cases of this type were admittedly few. The real difficulty was with the carrier of the recessive type of defect, who might be a normal person and capable of producing normal offspring. Here sterilization would have little effect. It had been mathematically calculated that if every albino was sterilized in every generation, the incidence of albinism would be reduced by only one half in 7000 years. Almost certainly mental deficiency was caused by the fortuitous combination of a number of defective genes in a number of different chromosomes that it was of a multiple recessive character. Therefore from a racial point of view little would be produced by sterilizing every mental defective.

Protection for the Certifying Physician

Sir Henry Brackenbury and the medical secretary of the association appeared before the government committee on the transmission of mental defect. Basing their views on the cognate matter of lunacy certification, they had told the committee that, if the sterilization of mental defectives was to be imposed, a single certificate would not be satisfactory, that, if there were two certificates, one should be given by the family physician and the other by an expert, that, if there were reasons why the family physician should not or would not certify, these should be stated on the certificate in justification of having gone to somebody else to get the certificate, and that there should be complete indemnity against actions at law being brought against the certifying physician, except on the ground of gross negligence.

Deaths from Electric Shock in a Bath

The danger of a person in a bath touching a defective electrical switch, in consequence of the water and bath furnishing a perfect "earth" for the current, is well known. But this danger has been manifested in a novel and striking manner in consequence of the use in a bath of an electrical heater and hair drier, respectively. Two inquests are reported in one day on young women who lost their lives in this manner. A girl, aged 17 years, on going to her bath took an electrical heater with her to warm the bathroom. After a few minutes her mother heard screams and forced the door open. She found the girl unconscious in the bath with the heater on top of her. She was taken to a hospital, where she died. In the second case a woman, aged 23, took a book and an electrical

hair drier to her bathroom. Her father found her with the drier in her right hand and the book at the end of the bath. When he touched her he got a shock himself, the handle of the drier being saturated and the current still on. The drier, which the girl had had for two years, was poorly insulated. A third inquest is reported on the same day in which a man, aged 39, was taking a bath when his mother smelled smoke and found him on top of an overturned electrical radiator. His clothes had caught fire and he was badly burned and died almost immediately. He was recovering from an attack of influenza, and it is believed that he fainted and fell over the radiator.

Shortage of Medical Officers in Army and Navy

A shortage of medical officers in the army and navy has again occurred because the conditions of service do not compare favorably enough with those of civil practice. At a meeting of the council of the British Medical Association, Surgeon Rear Admiral Thomas stated that the total establishment of the naval medical service was 402, while the strength was only 325, there being a shortage of 77. Many surgeon commanders had now to do the routine work formerly done by junior officers, because of shortage of the latter. The pay of single officers compared unfavorably with income obtainable on shore, and prospects of promotion were uncertain. It was also stated that the difficulty created by the early retiring age of 50 and the inadequacy of the pension was acute. Speaking for the army, Major General Hannay said that the pension on retirement was inadequate and that an officer was usually unable to save while in the service. Grievance was also felt as to specialist pay. Many officers by hard work qualified as specialists and were not employed as such. The Council passed a resolution drawing the attention of the military and naval authorities to the proposals for the improvement of the terms and conditions of service, submitted by the association to the government in 1931.

The Infectious Origin of Cataract

Dr Lavagna, who for years has been doing research on the infectious origin of cataract, gave recently some results of his investigations. Since Romer and Dor's reports were published it has been accepted that disorders in the crystalline lens, leading to the formation of cataract, are the result of hydrolysis and the retention of cellular poisons originating elsewhere in the organism. Lavagna believes in an infectious origin. The increase of lipoids observed in the tissues of a cataract is, in his opinion, a defense reaction of the organism against a chronic infection, for similar reactions are observed in septic gangrenes caused by certain anaerobic bacteria. Cataract is transmissible to the guinea-pig by intra-ocular inoculations of an emulsion of cataract tissue. An emulsion of human cataract introduced subcutaneously, or even by mouth, causes cataract to develop in animals in 60 per cent of the trials, which proves that there is a special virus manifesting a veritable tropism for the lens. A bacteriologic examination of smears of the tissue of fifty cataracts showed bacteria in only 20 per cent of the cases, but the cultivation of this tissue in aerobic and anaerobic mediums gave positive results in 90 per cent. The micro-organism most commonly encountered is a facultative anaerobic diplococcus, which grows readily in deep implantations in gelose. Its morphology may vary, one finds two strains, one form being streptococcic and twice as abundant as the other, which is bacillary. The inoculation of these cultures into animals causes cataract eighty times out of a hundred when it is applied to the eyeball or to the conjunctiva. In experiments made with other bacteria, the only ones that

produced somewhat similar lesions were certain diplostreptococci isolated from rheumatic lesions, a strain of hemolytic streptococcus obtained from the Institut Pasteur, and a strain of *Clostridium welchii*. Lavagna prepared an immunizing serum from cultures made with various strains derived from human cataracts and killed by means of heat. If an injection of this vaccine is applied to the animal a month before the virulent culture is injected, cataract does not develop. If the vaccine is applied less than one month before the inoculation, it protects in only half the cases. Lesions are produced in the other half, but they remain translucent and never invade the whole lens. Attempts to treat cataract in man by means of this vaccine gave encouraging results. The functional disorders are attenuated, and the opacity of the crystalline lens remains in the primary stage.

Action of the Posterior Lobe of the Hypophysis in Headache

Carnot, Caroli and Cachera gave a series of injections of the posterior lobe of the hypophysis to patients with biliary disorders with a view to determine the functioning of the bladder, it happened that these injections were given to patients suffering also from bad attacks of migraine, and there was observed in a number of cases a rapid and lasting disappearance of the headache and the nausea. Following these observations, they gave this treatment to patients with various types of headache. The patients were affected with migrainoid pains associated with dyspeptic disorders other than gallbladder disease. Some were suffering from headache that had no relation with digestive disturbances, headache associated with seasonal "colds," or with migraine of menstruation. More than twenty patients were treated. Nearly all experienced relief within a few minutes. At first it was given subcutaneously, but the effect was the same when the powder of the hypophysis was introduced within the nose. In studying this sedative action, the authors abandoned the theory that it was associated with emptying of the bladder and the drainage of bile. They considered the effect of the hypophysis on the cerebral blood supply or on the pressure of the cerebrospinal fluid. The action of the hypophysis on the cerebral circulation resembled that of ergotamine tartrate, the therapeutic value of which in migraine is well known. Changes in the pressure of the cerebrospinal fluid are usually in the direction of hypertension.

The Crusade Against Rats

Rats are carriers of the plague, exanthematic typhus, sodoku, and possibly hemorrhagic spirochetosis. These animals likewise damage property, the total amount of which for France and French North Africa exceeds a billion francs (\$40,000,000) a year. Two international congresses have already been held in Paris to study the best means of destroying these rats and in a previous letter reference was made to their rather fallacious conclusions. Dr. Loir, who is head of the public health service in Havre and also a nephew of Pasteur, has found a simple solution of the problem. It consists simply in training a certain breed of cats especially adapted to catch rats. He established at Havre a cat farm where he breeds a large species of cat which has been constantly under special training as rat catchers. The results have been excellent. Not a single rat can now be found in the city of Havre. These cats are intelligent and it does not take them long to locate rats. Impressed by these results, Mr. Herriot, mayor of Lyons, requested Dr. Loir to apply his method to the abattoirs in that city. A sufficient number of cats were placed in the abattoirs of Lyons and these buildings were rid of rats within a few weeks. The same excellent results were obtained with this method in a large warehouse in Paris. An appropriation has been made by the municipal council of Paris to establish a farm on which the cat animals may be raised.

Harmonious Thinking in Biology

Prof. August Bier addressed recently the Berliner Medizinische Gesellschaft on the subject of "Harmonious Thinking in Biology." Bier, to whom all members of the medical profession listen eagerly on all occasions, expressed himself somewhat as follows. Harmonious thinking presupposes consideration from widely different points of view, and, particularly, from opposite sides of a question. The world thus far has done but little harmonious thinking. In fact, science, during the past hundred years, has got quite out of the habit of thinking harmoniously. Our great theories, and, particularly, our biologic theories, are suffering from a onesidedness. The fate that all great theories, more or less, must suffer of being first dogma, then rejected and finally again recognized to a limited extent, Bier illustrated by citing the history of darwinism. The fundamental weakness of all great theories is the belief of their proponents that the theory constitutes the truth, whereas it represents only one truth. The theory views only one side of the subject. To approach as closely as possible to reality, one must consider a subject from various sides, and, particularly, from opposite sides. This Bier calls harmonious thinking. The honor and authority of science require that harmonious thinking be generally practiced. If not, science comes to be held in slight esteem by the masses, who say "What kind of science is this that today rejects what yesterday it recognized?" Harmonious thinking does not, by any means, exclude the onesided theory, on the contrary, the abstraction is needed for successful scientific work, scientists must, however, clearly understand that every scientific theory deals with great abstractions, and that with such abstractions one can approach the subject to be studied just as well from the opposite side. Both sides are, as a rule, equally true, if one remains conscious of this restriction, and equally false, if one loses sight of this fact.

Premature Child Develops Normally

In the medical literature there are numerous reports of the normal development of persons who were born prematurely. But reports on very small children born prematurely, extending over a number of years or decades, are rare. Professor Rietschel of Würzburg has published an instructive case in *Streiters Zeitschrift für Krankenpflege und Gesundheitsfürsorge*. When Rietschel was director of the Home for Infants in Dresden, a girl baby 35 cm long and weighing 940 Gm was admitted ten days after birth. It was decided that the child must have been born from two and one-half to three months before term. During the first few days after admission, the child's weight dropped to 900 Gm, whereupon it was placed in an incubator. It was fed with great care and after a little over eight months was returned to the parents weighing 2500 Gm. It has remained their only child, its present height being 155 cm and its weight 45 Kg, and it is otherwise normal. The young woman now 23 years old, is a music teacher.

League Against the Formation of Political Groups in the Medical Profession

There are in Germany a number of medical societies whose history extends over a period of 100 years or more. They were created for the most part for the exchange of scientific experiences for deliberation on matters of public health, or for social intercourse with one's colleagues. Later questions of professional politics began to come up, the discussion of which was relegated to a great extent to the *Deutscher Ärzteverein*, which today still is the syndical organization of German physicians. Closely associated with this league and under the

same chairman, is the economic syndical organization, which is called, after its founder, the Hartmann league.

While occasionally, in some local societies, political trends have gained the upper hand, the leagues mentioned have always opposed the growth of any such tendencies and have seen that the solidarity of the German medical league, in all matters pertaining to professional problems, has been preserved.

A group of physicians with socialist tendencies has, however, created a special organization, with a membership that supports certain political views and social movements. Physicians belonging to the national socialists followed their example and formed a second special organization. Of late there has been a movement, especially in western Germany, to organize a special professional group among the Catholic physicians, on the basis of their political and social views. The directorate of the *Deutscher Aerzteverband* is watching this movement with great anxiety, as was revealed by the discussion on the subject at its last session. A split in the medical profession is feared. Many speakers emphasized that the physician should be primarily a help to patients. At no time has there been such a need of influencing the souls of patients as at present, which presupposes a body of physicians that is able to understand human problems and is disposed to take a sympathetic interest in everything that concerns the affairs of their patient. The question is asked, How can the humane mission of the physician be realized if the social, political and religious relations of the physicians are overemphasized and brought under questionable influences? By openly calling attention to the effects of this trend of the times, from the standpoint of unity and the preservation of the "ideal physician," it is hoped that the large number of physicians who have joined the movement, unconscious of the danger, may be brought to their senses.

The Growth of German Hospitals

In a recent address before the *Berliner Gesellschaft für öffentliche Gesundheitspflege*, Dr. Goldmann, of the federal ministry of the interior, described the development and the work of German hospitals. In the past fifty years, German hospitals have more than doubled in number, and the number of sick-beds has increased more than fivefold. Less than two years ago there were about 4,000 hospitals with about 400,000 beds. The number of persons treated annually in hospitals has increased, within fifty years, from half a million to nearly 4,000,000, nearly an eightfold increase. The mortality of many diseases in the hospitals has been reduced, for example, the mortality from appendicitis has dropped from 45 per cent to 16 per cent. At present, Germany ranks among the first countries in the proportion of available hospital beds to the number of inhabitants (62:1,000).

Postoperative Lung Complications

Addressing the *Berliner Gesellschaft für Chirurgie*, Professor Sauerbruch discussed the important subject of postoperative lung complications. He called attention first to the various types of pneumonia: (1) aspiration pneumonia, (2) anesthesia pneumonia, which is becoming more rare, (3) infarct pneumonia, characterized by inflammation about an embolus, (4) massive collapse of the lung, which is often wrongly regarded as pneumonia, and is due to occlusion of a bronchus, and (5) influenzal pneumonia. There are other conditions that are directly connected with the operation: 1. Reaction due to taking cold (Sauerbruch noted that the cases of postoperative pneumonia decreased when patients were no longer transported, as formerly, through the open air to an adjacent pavilion). 2. The shock reaction of the lung, which is reflected in a severe pulmonary hyperemia. 3. Allergic reactions, first toward substances used for general or local anesthesia, and secondly toward protein disintegration products. 4. Toxic reaction, every extensive operation produces toxins that enter the blood, particularly frequent, owing to this cause, is pneumonia following operations

on the pancreas. 5. Cardiac disturbances, which may be significant in causing postoperative pneumonia. Inadequate respiration is also an important factor, especially after operations on the upper part of the abdomen, owing chiefly to the fact that the tonus of the diaphragm becomes impaired. Epinephrine, venesection and quinine preparations often help more than digitalis and similar medicaments. Opiates are sometimes indicated. One must not forget that morphine has a central effect on respiration.

Report of the Red Cross

The *Preussischer Landesverband vom Roten Kreuz* and its provincial chapters have published a report on their activities during the past fiscal year. Formerly complaints were heard at the general assemblies that the Red Cross did not have sufficient work to perform, now, owing to the economic situation, all the regular forces and the auxiliaries of the Red Cross are being used to their fullest capacity. Few of the communes are able to supply the needs of all their dependents, so that everywhere the voluntary welfare movement has to be strengthened. In unemployment aid, welfare aid for the sick, and the small garden movement, the Red Cross has collaborated energetically. A new task for the Red Cross is the training of the civil population to protect itself against air attacks. The International Red Cross has protested, many times, against the use of chemicals in air attacks, but so long as air attacks with chemicals are not generally prohibited, the Red Cross regards it as a duty to aid, with all its power, the authorities in their endeavors to protect the civilian population against loss of life that may result from such air attacks.

ITALY

(From Our Regular Correspondent)

Dec 31, 1932

Congress of Urology

The eleventh *Congresso nazionale della società italiana di urologia* was held in Rome, in the Great Hall of the *Clinica chirurgica* of the university. Professor Bruni, the president, in opening the session recalled the figure of Antonio Scarpa, the eminent urologist and general surgeon, the centenary of whose death was celebrated this year by special ceremonies. In the matter of extraction of bladder stones during Scarpa's time, the perineal route and the rectovesical method struggled for supremacy. Scarpa perfected the perineal method and published an article in which the preperitoneal space, called now Retzius' space, was minutely described for the first time.

RENAL SURGERY

The first topic on the program was "The Remote Orthopedic and Functional Results of Conservative Renal and Ureteral Surgery." The official speakers were Prof. G. Nicolich of Trieste and Prof. V. Raffo of Genoa. Professor Nicolich endeavored to show what improvements in function are obtained by conservative operations and what functional lesions may possibly be due to such operations. He examined persons who had been operated on for decapsulation of the kidney, nephropexy, nephrotomy, nephrolithotomy, nephrostomy, pyelolithotomy and ureterolithotomy, doing urinalysis and simple radiography, but he did a minimum of instrumental examinations (cystoscopy, catheterization of the ureters, pyeloscopy, pyelography). The patients were operated on at the *Ospedale di Trieste*, in which, during the period 1897-1932, 332 conservative operations on the kidney and 36 conservative operations on the ureters were performed. Of the former, 299, and of the latter 33, patients survived. In 77 of the renal cases (26 per cent) and in 13 of the ureteral cases (39 per cent) reexaminations were made later. On the basis of the examinations, the speaker brought out that little or no damage results to renal function or to the excretory apparatus from decapsulation, capsular nephropexy and pre-

lithotomy, whereas damage may result from nephrotomy, the conservative operations proposed for hydronephrosis, renal enervation and the resections, anastomoses and plastic operations affecting the ureters. Nicolich surveyed then the remote results of the conservative operations in renal malformations and in traumatic lesions of the kidney, such cases were rarely treated in the urologic department at Trieste. With regard to operations for floating kidney, the speaker considers that nephropexy is indicated only in cases of high degree of mobility not associated with enteroptosis or which present inflammatory processes due to the abnormal mobility. There were nine patients operated on by nephropexy, in five of whom a descending pyelo-ureterography was done. The results varied notably. The best results were in persons whose abdominal walls were not relaxed. In nephrosis and in chronic glomerulonephritis, the speaker did not observe favorable results from decapsulation, but more frequently he noted a rapid exacerbation of the disease. A study of the remote results of conservative operation for nephrolithiasis presents many difficulties, since, if the renal functioning and the pyelo-ureteral functioning are changed, it is difficult to determine whether the changes are due to the operation or to the recurrence of calculosis, infections, toxic products of exchange or modifications in the circulation. In the urologic department of Trieste there were performed, up to February, 1932, 226 conservative operations for nephrolithiasis, and 162 nephrectomies.

The number of nephrectomies is high, but in all cases it was a question of kidneys with grave infectious or hydronephrotic parenchymal lesions or of large and multiple calculi. On the whole, the remote results of these conservative operations were good as regards the functioning of the kidney and with respect to its position. In the majority of cases a dilatation of the calices, sometimes associated with a dilatation of the pelvis, was observed. In the cases of bilateral lithiasis, the remote results were favorable as regards the general condition of the patients and the subjective disturbances but less favorable with respect to recurrences and the anatomic and functional changes of the kidney and of its excretory apparatus. With regard to conservative operation in hydronephrosis, the speaker regards resections of the ureter as contraindicated. He believes that good results can be obtained by means of nephropexy and freeing the ureter from adhesions (ureterolysis). Ureterolithotomy is considered a benign operation that never has a damaging effect on the tonicity and motility of the ureters.

Professor Raffo, who spoke on the same subject, examined eighty-five patients previously subjected to conservative surgical intervention on the kidney and ureters. He concluded that the kidney is not infrequently displaced after conservative operations that have not been supplemented by nephropexy, but rarely does this displacement produce notable disturbances in the functioning of the kidney and of its excretory tracts. He found that the recurrences of calculi are rather frequent after conservative operations especially after nephrolithotomy. In cases of ureteral lithiasis treated with ureteral lithotomy, he found 18.48 per cent of recurrences. As regards conservative surgical treatment of floating kidney, the speaker concluded that nephropexy usually gives favorable results especially if done to overcome obstruction due to the renal mobility.

As regards hydronephrosis, Raffo stated that in selected cases the conservative operation may give satisfactory remote results. Intection is not an absolute contraindication to a conservative operation. In so-called small hydronephrosis without apparent caliceal dilatation, nephropexy gives important results. Sometimes the mere division of an aberrant vessel brings a clinical recovery. Plastic operations are not to be rejected absolutely.

Several theoretical communications were presented. Niscio of Bari reminded that in discussing renal calculi the speakers omitted themselves to statistic. He would have preferred

to have the patients studied from the point of view of the constitution, the diathesis, the nervous system, the sympathetic system and, above all, the parasympathetic system.

At the congress next year at Pavia, the topic will be "Endoscopic Treatment of Disorders That Cause Obstruction of the Neck of the Bladder." The newly elected president of the Società italiana di urologia is Professor Gardini.

Meeting of National Council of Research

Honored by the presence of the "head of the government," the Consiglio nazionale delle ricerche held recently a session in Rome. Senator Marconi reviewed the activity of the council during the year.

With regard to medicine, the researches dealt mainly with hygiene, the epidemiology of typhoid, and *Ancylostoma duodenale*, the action of ultraviolet rays, the tuberculous ultravirus, rheumatism and the ultramicroscopic elements of the virus of malaria.

BUCHAREST

(From Our Regular Correspondent)

Jan 20, 1933

The Ninth International Congress of Medical History

The Ninth International Congress of Medical History was opened in Bucharest, Sept 10, 1932, in the halls of the Ateneul Roman. Charles II, king of Rumania, the honorary president of the congress, was present. The opening address was given by Dr. Gomoiu, formerly secretary of the ministry of public works, now amalgamated with the ministry of public health. The Rumanian premier, Alexandru Vajda, also a physician, discussed the importance of this relatively young science and expressed thanks to the 137 representatives of twenty-three states and forty-eight universities, who came from all parts of the globe. The scientific program was taken up Monday in the hall of the legal faculty of the university, under the presidency of Professor Castiglioni. Prof. Ata Galip of Istanbul read a paper on "The Evolution of the Medical Sciences in Turkey." Prof. Hector Sarafidi read a paper written by Aiheni Kisis on 'History of the Progress of Medical Science in Greece', Ali Mihali of Vlorë took up "The Evolution of Medical Science in Albania", Stoianoff of Sofia, Bulgaria, and Jujo Thaller of Zagreb, Croatia, lectured on the early history of medicine in their respective countries.

Professor Suhayl of Istanbul discussed the evolution of the Turkish hospitals. It was interesting to learn that fairly well equipped hospitals were functioning in Turkey 2000 years ago. Drs. Meyersohn and Halevy, both of Bucharest, read a paper on Jewish physicians practicing in Rumania in the fourteenth to eighteenth centuries. Panaitescu of Sulina, Rumania, who read a paper on the history of public health service in the Danubian ports, emphasized that the extermination of malaria in these ports was a result of the research of the late Ronald Ross of England. Samarianu of Calarasi, Rumania, read a paper on the evolution of the Rumanian hospitals and other public institutes which he said were copied from the French system. The public health laws of Rumania also were offsprings from the French. Sarafidi of Constanza, Rumania, lectured on the evolution of the well known malaria nest in the Dobruja, the most backward of all Rumanian provinces. The number of physicians there is small owing to the great poverty of the inhabitants and private practice is negligible. The salary paid by the state does not compensate for the risk a physician takes because of the prevalence of infectious diseases. On the third day of the congress, Capparoni of Rome and Giordano of Venice related the history of plague in Italy. They said that the first records dealing with plague in Italy were made by a physician called Rurus who came from Ephesus, in the reign of the emperor Trajan. Plague was brought into

Italy sporadically from Libya, Egypt and Syria. The home of plague at that time was northern Africa. The first epidemic in Italy occurred in the sixth century. In the great epidemic of the fourteenth century, called the black death, Italy was included. On the fourth day, Professor Bilkiewicz of Cracow, Poland, read a treatise on the future of the history of medicine. He believes that the study of medical history ought to be required in all universities. Professor Fischer of Vienna discussed the development of gynecologic surgery, and Professor Goldschmidt of Frankfurt the importance of the pathologic and anatomic work and the achievements of Cruveilhier.

On the fifth day, Dr. Gomoiu read a paper on the recent history of housing and sanitation in Rumania. He said that with the exception of Bucharest there had been no housing problem in Rumania prior to 1880, it came with the rise of industrialism. Legislation enacted in the period of 1880-1898 encouraged the erection of inexpensive dwellings for the working classes by granting tax exemptions to cooperative building and loan associations. In 1898 an impetus was given to the housing movement by the establishment of a central housing commission and by the foundation of the Institute for the Building of Popular Houses. The erection of houses in large railway centers for railway employees was encouraged and financed by the government. To meet the housing crisis following the war, a fifteen year exemption from taxes was granted for new buildings and generous credit was supplied by state subsidized banks, more especially to cooperative building associations—often cooperative only in name. Since 1922 a new trend has been given to the effort. Tax exemption has been extended to small apartments in order to encourage private enterprise to meet the demand for houses, special credit facilities are afforded to house building societies. At the end of 1927 the housing crisis had not been solved, but it was much less intense.

As to sanitation, the prevention and treatment of venereal disease has been stressed. A nation-wide antituberculosis campaign has been started, working through provincial associations regulated by different acts issued between 1902 and 1910. Through them, all the efforts in this direction are coordinated, and special dispensaries, sea and mountain sanatoriums, hospital accommodations and open air schools for children are provided. The funds heretofore assigned are proving inadequate and means to increase them are being studied in connection with the compulsory insurance of industrial workers against tuberculosis enacted quite recently. A law enacted in 1928 provides for the opening of municipal and provincial hygienic laboratories for research work in hygiene.

Dr. Gabel of Poland read a paper on eye diseases known among the ancient Egyptians and Arabs. Professor Suhayl exhibited a medical manuscript of the fifteenth century. Szumowsky of Cracow, Poland, reported an elaborate study in which he endeavored to prove the importance of medical history as a required subject in the medical curriculum. Professors Lavastine and Vinchon discussed the state of medical science in Persia in the seventeenth century. Vaian of Bucharest read a paper in which he tried to prove that the first Rumanian medical historian was Prince Cantemir. Demeter Halevy of Bucharest discussed medical references to the function of the Jewish rabbis in the eighteenth century.

After the congress the members visited the seaside and climatic health resorts, where they were entertained with magnificent banquets. They were greatly pleased with the hospitality of the hosts.

The Rumanian postmaster general issued special stamps to commemorate the occasion. The one leu stamp illustrates the centenary of the foundation of the civilian hospitals, 1832-1932. On the ten lei stamp is a reproduction of Trajan's bridge, the symbol of the road on which the ancients came into Rumania. It shows Aesculapius and Hygeia coming into Rumania on a

boat on the Danube, in the background is an Istrian lighthouse, in reference to the culture of the old Dacia, on the left side of the stamp is the profile of the king. The special stamps illustrate the theme of the congress, which was the development of the medical sciences in Rumania and in the Balkan countries.

Every one present was given also a bronze souvenir coin on one side of which was shown Aesculapius and Hygeia, just as they were pictured on a stone found at Constanza, while drilling a well. The other side of the coin illustrates the conception of medicine, as it appeared on a medal which was coined during the reign of the emperor Severus.

BELGIUM

(From Our Regular Correspondent)

Jan 17, 1933

The Brussels Medical Week

The recent Brussels medical week (*journées médicales*) was a complete success. In his opening address, the minister of health discussed the sanitary condition of the country. In 1830 Belgium, with a population of 4,000,000, had about 100,000 deaths, in 1930 Belgium, with a population of 8,000,000, had about the same number of deaths (100,000). In 1920, 1,459 cases of typhoid were reported, in 1931, 150 cases. In 1920, 6,409 cases of diphtheria were recorded, in 1931, 1,669 cases. In 1929, 500 cases of poliomyelitis were notified, in 1931, 59 cases. There were no cases of plague or cholera. In 1910 there were 163 deaths per 10,000 inhabitants from tuberculosis, in 1930 there were only 118 deaths from tuberculosis per 10,000 of population.

Public health work in Belgium is accomplished by the collaboration of medical practitioners and the government health services. The government decided not to delegate the protection of the public health to a special body of medical sanitarians. Such an organization would no doubt be impractical in Belgium, where private medical practice has been deeply entrenched since ancient times. It was decided, therefore, to divide the duties involved in the protection of the public health between the physicians who protect the individual and the family, and the health officers who protect the people as a whole. It has been found that the best way to protect the general interests, in the matter of health, without damaging private interests, lies in preserving a proper balance between the respective duties of each party, and in the perfect coordination of their activities. The practitioner thus becomes the indispensable guide of the health officer.

THE PHYSICIAN AND THE COURTS

In discussing "The Civil Responsibilities of the Physician," Dr. d'Ernst took as his basis the research of Professor Juliard of Geneva. He said that, in view of the present state of mind of a physician's clientele and the tendencies of the courts, any medical act may bring the most cautious physician before the courts and result in his downfall. Certain startling decisions of the courts have compelled the *Société de chirurgie suisse* and the *Fédération des unions professionnelles suisses* to study the problem. The radiologists have likewise devoted a number of sessions to the consideration of this question.

Even though a physician is not found guilty of a professional misdemeanor, being summoned before a court of justice is a great annoyance. During the past few years the courts have been inclined to make the physician responsible for any discomfort that a patient suffers during a course of treatment, even though no charge of neglect or misconduct can be proved against the physician. Every physician should be well insured against such professional risks. In the opinion of Professor Juliard, a physician should insure himself against every possible untoward incident that may arise during a course of treatment.

SOCIAL MEDICINE

Dr Garozzi pointed out the steps taken in other countries in social medicine. He considered the origins of social medicine and of the social laws. He said that such movements date back to the most remote Greek and Roman antiquity. The physician should be without doubt the master mind in the social organization of public health. He defined then the notions of social medicine, social insurance, social hygiene and social pathology. It is important, if one is going to systematize, to make use of the recognized terminology. The author defined this terminology and outlined the role of each branch of social medicine. He noted the effects of unemployment on mortality, and the influences exerted by an occupation on the health of the individual. Social medicine should make special studies in biology and physiology, the hygienic conditions of work, the pathology of work, infections and occupational diseases. Social hygiene studies the legislative and economic measures capable of diminishing the consequences of disease. The social phenomena are of course in a constant state of flux. What was true yesterday may be no longer true tomorrow. The directors of social work should endeavor to look into the future, and university instruction should take account of these facts.

RESEARCH ON CANCER

Dr N Waterman mentioned the various methods of establishing predisposition to cancer. Physicochemistry has served as a basis for these researches. He took up his previous studies on the lysis of cancer cells in suspension, and the phenomena of agglutination in cancer. One can extract by means of ether the lytic and agglutinant substances of the cells of the reticulo-endothelial system. Experiments *in vivo* on these substances with a view to establishing a method of organotherapy are being carried on.

CANCER OF THE LARYNX

Dr L Van Den Wildenberg, professor of otorhinolaryngology at the Faculté de médecine de Louvain, discussed laryngeal cancer. He emphasized the need of an early diagnosis based on an examination with the laryngeal mirror and confirmed in all cases by a biopsy. As to what treatment is indicated, one is faced with the dilemma: surgery or irradiations. The author protested against the immediate employment of irradiation. In all operable cases, surgical intervention should be resorted to for which one of the three following methods may be indicated: laryngofissure, hemilaryngectomy, total laryngectomy. If one is in doubt between two procedures, the more extensive operation should be chosen. In case of a recurrence, the next more extensive operation may be done. Irradiations give good results in some cases but the cases are isolated and there is no way of foretelling the results. Irradiation, therefore, may be considered only as an adjuvant. Its indications are chiefly in inoperable cases or in the event that the patient refuses to submit to surgical intervention. When the tumor is extensive and it appears that total laryngectomy has not removed all of it, irradiation may be indicated to confirm the cure. If following total laryngectomy there is a recurrence, irradiation constitutes evidently the last therapeutic resource. But in all cases surgery is paramount and in the hands of an expert the operation is not particularly dangerous. The author projected on the screen recent portraits of a series of patients operated on, all of whom appeared to be in excellent health.

Treatment of Epitheliomas of Eyelids

Mr R Hubin of Liege states that since 1925 at the University Clinic of Liege, epitheliomas of the eyelids have been systematically treated with radium. The needle method is employed, doses of 1,800 and sometimes even 2,000 microcuries per square centimeter for a given thirty-six cases have been

treated. No recurrences have been observed. The percentage of complete recoveries was 88. In a few cases, the appearance of a slight xerophthalmia was noted. One case gave rise to a symblepharon. Three cases could not be followed up. The conclusions are therefore favorable to radium therapy. This treatment is not only more effective but also less mutilating than surgery.

TURKEY

(From Our Regular Correspondent)

Ankara, Jan 30, 1933

Government Monopoly of Drugs and Narcotics

Under the presidency of Gazi Mustapha Kemal Pasha, the council of ministers has assembled to formulate the policy that is to govern the amendment of the drugs and narcotics law. The bill will be presented at the reopening of the assembly. The international agreements of the 1923 conference at The Hague and the 1925 and 1931 conference at Geneva were given first attention. It has been decided that the three privately owned Istanbul laboratories where drugs and narcotics were manufactured, which last year were closed by the government because of violation of the law, will be refused permission to engage further in the manufacture of drugs and narcotics, and all other private manufacture is to cease. The amendment is to provide for special courts for the punishment of any one guilty of violating the law. The manufacture of drugs and narcotics for medicinal purposes in Turkey is to be carried on at a government laboratory, which also will make all exportations of crude opium. To limit the production of opium, special permission will have to be procured for cultivation. The cultivation of cannabis will be prohibited. The purpose of these measures is to make it impossible to grow more opium than is indispensable for legitimate export and for the supply of the government laboratory.

Outbreak of Scarlet Fever in Istanbul

A scarlet fever epidemic broke out in October among the preschool children and those in the primary schools. During the last week of October, 239 cases were reported, and during the last week of November, 291 cases. Sporadic cases have

Incidence of Scarlet Fever in Recent Years

Year	Cases	Deaths	Year	Cases	Deaths
1927	1,456	266	1930	1,638	204
1928	4,457	565	1931	682	101
1929	2,527	490	1932	1,791	95

been reported from other cities. Schools were not closed but the children were obliged to submit to the Dick test. The municipality opened ten immunization stations, where almost 75,000 persons were immunized. The vaccine was prepared at the serologic department of the Ankara Institute of Hygiene.

Increase in Consumption of Alcohol

At the annual meeting of the Green Crescent, the Turkish antialcohol society, measures were discussed for curbing the increase in the consumption of alcohol. According to the statistics of the alcohol monopoly, 5,736,232 liters was consumed in 1931 and there was an increase during 1932 of more than 500,000 liters. The Istanbul municipality has pledged to cooperate by revoking the licenses of automobile drivers who have caused a traffic accident while intoxicated. The society then decided to encourage the production and use of fruit drinks, to make use of educational films, pamphlets, posters, plays and slogans on the screen in motion picture houses, to establish clinics for alcohol addicts and to procure the cooperation of university students to establish antialcohol societies in their home communities.

Marriages

JAN DONALD SMITH Harrisburg, Pa., to Miss Geraldine Baker of Endicott, N. Y., Dec. 23, 1932

WALTER HARALI MINOR, JR., to Miss Elizabeth Van Antwerp, both of Mobile, Ala., February 11

JOHN L. HAMILTON, Barnesboro, Pa., to Miss Helen Wells of Steubenville, Ohio, Dec. 17, 1932

FREDERICK B. LITTELL to Miss Edna Slaughter, both of Norristown, Pa., Dec. 17, 1932

SOPHIA I. KIFFEGMAN to J. Harold Silliman, D.D.S., both of New York, Dec. 31, 1932

RALPH MAYO CLEMENTS, Luverne, Ala., to Miss Ima Carl Turner, February 19

Deaths

Clarence Albert Shore ☉ Raleigh, N. C., Johns Hopkins University School of Medicine, Baltimore, 1908, since 1908 director of the State Laboratory of Hygiene, member of the Society of American Bacteriologists, president of the Tri-State Medical Association of the Carolinas and Virginia, past president of the Wake County Medical Society, past president of the North Carolina State Board of Medical Examiners, instructor in biology, University of North Carolina, 1901-1904, aged 59, died, February 10, in the Rex Hospital, of mesenteric thrombosis

Robert Soutter ☉ Boston, Harvard University Medical School, Boston, 1899, member of the American Orthopedic Association, fellow of the American College of Surgeons, formerly instructor in orthopedic surgery at his alma mater, on the staffs of the Children's Hospital and Long Island Hospital, Boston, the Lawrence Memorial Hospital, Medford, the Massachusetts Hospital School, Canton, and the New England Peabody Home for Crippled Children, Newton, aged 62, died, February 21, in the Baker Memorial Hospital, of septicemia

Howard Wilson Levengood ☉ Santa Monica, Calif. Medico-Chirurgical College of Philadelphia, 1905, member of the American Academy of Ophthalmology and Oto-Laryngology and the Pacific Coast Oto-Ophthalmological Society, fellow of the American College of Surgeons, on the staffs of the Wilshire and Santa Monica hospitals, Santa Monica, and the Eve and Ear Hospital of Los Angeles, aged 50, died, January 30, of heart disease

William T. Pinkerton, Prairie Du Chien Wis., Louisville (Ky.) Medical College, 1879, member of the State Medical Society of Wisconsin, member of the board of education, aged 77, on the staff and formerly medical director of the Prairie du Chien Sanitarium and Hospital, where he died, January 31, of acute dilatation of the heart, chronic myocarditis and nephritis

Caryl Ashby Potter ☉ St. Joseph, Mo., Johns Hopkins University School of Medicine, Baltimore, 1911, fellow of the American College of Surgeons, served during the World War, on the staffs of the Missouri Methodist and St. Joseph's hospitals, aged 46, died, January 23, in Kansas City, of hypertension and arteriosclerosis

Louis Wardlaw Haskell ☉ Memphis, Tenn., Johns Hopkins University School of Medicine, Baltimore, 1903, chief of the division of surgery and professor of surgery, University of Tennessee College of Medicine, aged 54, surgeon in chief to the Baptist Memorial Hospital, where he died, February 10

John L. Miller, Corning, N. Y., University of Buffalo School of Medicine, 1894, member of the Medical Society of the State of New York, formerly mayor of Corning, health officer of the towns of Caton and Corning, school medical inspector and member of the state assembly, died, January 6

William Oscar Whittle, Baltimore, University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore, 1916, member of the Medical and Surgical Faculty of Maryland, served during the World War, aged 46, died, February 2, of carcinoma of the stomach

Charles D. Frederick O'Hern ☉ Tulsa, Okla., College of Physicians and Surgeons, Baltimore, 1907, fellow of the American College of Surgeons, past president of the Oklahoma State Board of Medical Examiners, aged 54, died, Dec. 10, 1932, of organic heart disease

George De Vere Miller ☉ Cadillac, Mich., Rush Medical College, Chicago, 1902, president of the Tri-County Medical Society, fellow of the American College of Surgeons, chief of staff of Mercy Hospital, aged 57, died, February 16, of carcinoma of the prostate

Jacob Bruce Patterson ☉ Wooster, Ohio, Washington University School of Medicine, St. Louis, 1907, at one time medical missionary, formerly county coroner, aged 56, died, February 15, in a hospital at Berca, of injuries received in an automobile accident

George Rice Barden ☉ Providence, R. I., Bellevue Hospital Medical College, New York, 1896, fellow of the American College of Surgeons, on the staffs of the Homeopathic Hospital and St. Joseph's Hospital, aged 64, died, January 29, of influenza

Frank William Lose, Decatur, Ind., Northwestern University Medical School, Chicago, 1922, past president of the Adams County Medical Society, formerly on the staff of the Adams County Memorial Hospital, aged 38, died, February 5, of cellulitis

Alanson Halden Jones, Los Angeles, University of Southern California College of Medicine, Los Angeles, 1908, served during the World War, aged 50, died, January 22, in the Veterans' Administration Hospital, Palo Alto, Calif., of heart disease

Donald Edward Davenport ☉ Takoma Park, Md., College of Medical Evangelists, Los Angeles, 1915, formerly a medical missionary, on the staff of the Washington (D. C.) Sanitarium and Hospital, aged 46, died, February 15, of brain tumor

Eugene J. Donohue ☉ Antigo, Wis., Northwestern University Medical School, Chicago, 1906, past president of the Langlade County Medical Society, on the staff of the City Hospital, aged 52, died, February 15, of nephritis and influenza

Elmer A. Kell ☉ Hanover, Pa., Baltimore Medical College, 1900, past president of the Wyoming State Medical Society, formerly mayor and president of the school board of Rawlins, Wyo., aged 54, died, January 31, of heart disease

Bruce Webster Baker, Cordell, Okla., University of Louisville (Ky.) School of Medicine, 1914, member of the Oklahoma State Medical Association, aged 43, died, February 14, in the Clinton (Okla.) Hospital, of cholecystitis

Fenwick Rieff Deans, Miami, Okla., Barnes Medical College, St. Louis, 1897, Illinois Medical College, Chicago, 1907, member of the Oklahoma State Medical Association, served during the World War, aged 67, died, Dec. 31, 1932

Milton Hahn ☉ Arkansas City, Kan., Johns Hopkins University School of Medicine, Baltimore, 1907, served during the World War, aged 50, died, February 13, in the Research Hospital, Kansas City, Mo., of coronary occlusion

Arthur Le Sage, Fowler, Ind., Northwestern University Medical School, Chicago, 1898, member of the Indiana State Medical Association, formerly county coroner, aged 60, died, January 26, of acute dilatation of the heart

Mace H. Bell ☉ Vicksburg, Miss., Memphis (Tenn.) Hospital Medical College, 1900, member of the American Academy of Ophthalmology and Oto-Laryngology, aged 52, died, February 1, of Addison's disease

John Knox Miller, Greeley, Colo., Rush Medical College, Chicago, 1883, aged 78, formerly on the staff of the Greeley Hospital, where he died, January 28, of arteriosclerosis and Parkinson's disease

James Lewis Perdue, Greenville, Ala., Medical College of Alabama, Mobile, 1875, member of the Medical Association of the State of Alabama, aged 81, died, Dec. 17, 1932, of cerebral hemorrhage

Martin Earl Harrell, New Madison, Ohio, Eclectic Medical College, Cincinnati, 1917, served during the World War, aged 43, was found dead, February 7, of chloroform poisoning, self-administered

Emanuel Lucas Hemion, Paterson, N. J., Jefferson Medical College of Philadelphia, 1894, member of the Medical Society of New Jersey, aged 62, died suddenly, February 20, of heart disease

Alexander Christy Dempster ♂ Uhrichsville, Ohio, Ohio Medical University, Columbus, 1896, past president of the Tuscarora County Medical Society, aged 66, died, February 7, of heart disease.

John E Henshall, Lakeland, Fla., Hahnemann Medical College and Hospital of Philadelphia, 1895, aged 74, died, January 7, in the Morrell Memorial Hospital, of carcinoma of the prostate.

Frederick Hooker, Syracuse, N Y, Chicago Homeopathic Medical College, 1886, for many years on the staff of the Syracuse General Hospital, aged 66, died, February 4, of pneumonia.

Joseph Edouard Huard, Fall River, Mass., College of Physicians and Surgeons, Baltimore, 1896, aged 60, died, Dec 30, 1932, of coronary occlusion, arteriosclerosis and hypertension.

Sheldon Leavitt, Chicago, Hahnemann Medical College and Hospital, Chicago, 1877, aged 84, died, February 1, in the Chicago Memorial Hospital, of uremia and prostatic hypertrophy.

Frank Emmett Gearon ♂ Chicago, University of Illinois College of Medicine, Chicago, 1909, on the staff of St. Anne's Hospital, aged 52, died, Dec. 23, 1932, of myocarditis and nephritis.

Martin L Dalton, Montvale, Va., University College of Medicine, Richmond, 1899, member of the Medical Society of Virginia, aged 56, died, January 2, of bronchopneumonia and influenza.

James Montgomery Irving, Cincinnati, Chicago College of Medicine and Surgery, 1913, formerly on the staff of the Longview Hospital, aged 55, died, Dec 19, 1932, of heart disease.

John Augustus Beuermann, New York, Universität Zurich Medizinischen Fakultät Zurich Switzerland, 1894, aged 70, died, January 2, in the Lenox Hill Hospital, of cerebral hemorrhage.

Elbert Hays Wilkes ♂ Little Rock Ark., College of Physicians and Surgeons, Little Rock, 1909, aged 54, died, January 25, in Chicago, of carcinoma of the stomach.

Thomas Franklin McGee, Lubbock, Texas Missouri Medical College St Louis 1884 aged 82, died February 2, of hypertrophy of the prostate and chronic nephritis.

Charles Kinsey Conard, Mount Vernon, Ohio, Homeopathic Hospital College Cleveland, 1890, member of the Ohio State Medical Association, aged 67, died, January 7.

Nathan Henry Reeve, Bristol Tenn., University of Nashville Medical Department 1874 Civil War veteran aged 85 died, January 26, of chronic bronchitis and senility.

Bernard J Murray ♂ Philadelphia, Medico-Chirurgical College of Philadelphia 1892, aged 73, died, February 14, in the Germantown Hospital, of cerebral hemorrhage.

Ernest Hollingsworth, Washington Ind University of Louisville (Ky) School of Medicine 1898 city health officer, aged 56, died February 4, of diabetes mellitus.

Edward Henry Moriarty, Mount Clemens Mich., Grand Rapids Medical College 1906 aged 50 died, January 30, in a local hospital, of chronic nephritis and uremia.

Theodore Gourdin Kershaw ♂ Augusta, Ga Medical College of the State of South Carolina, Charleston 1904, aged 49 died January 26, in Asheville, N C.

William F Bourne, Staten Island N Y University of the City of New York Medical Department 1879, aged 77, died February 16 of carcinoma of the throat.

Dail Willson Conger, Montesano Wash St Louis University School of Medicine 1906 aged 48 died, January 10, of a self-inflicted bullet wound in the head.

Bascom William Hamrick, Lee Fla Georgia College of Eclectic Medicine and Surgery Atlanta 1914 aged 52, died January 20 in a hospital at Valdosta Ga.

John F Ausmus, Speedwell Tenn Tennessee Medical College Knoxville 1892 aged 69 died February 11 in the Middleboro (Ky) Hospital of pneumonia.

James Robert Watson Danville Ill Rush Medical College Chicago 1880 aged 69 died Dec 29 1932 in the Lakeview Hospital of cerebral hemorrhage.

Andrew Evan Hardin San Diego Caln Cooper Medical College San Francisco 1897 aged 61 died suddenly January 16 of ruptured aortic aneurism.

Joseph Alphonsus Kelly, Yonkers N Y University of Michigan Medical School Ann Arbor 1898 aged 72 died February 5 of cerebral thrombosis.

Leroy L Imes, Denver, Physio-Medical College of Indiana, Indianapolis, 1904, aged 56, died, January 19, of pulmonary tuberculosis and chronic myocarditis.

Alleyne M Baldwin, Cleveland, Western Reserve University Medical Department, Cleveland, 1891, aged 63, died, February 4, of cardiorenal disease.

Frederick Washington Duncker ♂ Newark, N J, Bellevue Hospital Medical College, New York, 1866, aged 87, died, January 28, of heart disease.

William Herbert Crowell, Whiteville, N C University of Maryland School of Medicine, Baltimore, 1895, aged 66, died, February 12, of pneumonia.

Harold Percival Blodgett ♂ Leominster, Mass., Tufts College Medical School, Boston, 1902, aged 53, died, February 16, of cerebral hemorrhage.

William Franklin Hamilton, Tomahawk, Ark., University of Arkansas School of Medicine, Little Rock, 1908, aged 65, died, January 8, of nephritis.

Charles Thomas Adams ♂ Philadelphia, Jefferson Medical College of Philadelphia, 1896, aged 71, died suddenly, January 14, of chronic myocarditis.

Leander B Dean, Kenova, W Va., Kentucky School of Medicine, Louisville, 1894, aged 72, died, February 5, in the Louisa (Ky) General Hospital.

Benjamin P Wall, Berkeley, Calif., Hahnemann Medical College of Philadelphia, 1880, aged 79, died, January 20, of carcinoma and arteriosclerosis.

Nellie Laura Clark, Clovis, Calif., Medical Department of Omaha University, 1898, aged 64, died, January 23, of arteriosclerosis and epilepsy.

John H Blake, Wenatchee, Wash Kansas City (Mo) Medical College, 1893, aged 70, died, February 3, of a fractured hip received in a fall.

Oscar Howe Holder, New York, Harvard University Medical School, Boston, 1892, aged 66, died, January 15, of carcinoma of the left lung.

William Emory Neiberger, Clearwater, Fla., Chicago Homeopathic Medical College, 1882, aged 80, died, February 7, of pulmonary tuberculosis.

William Emmett Cuff, New York University of the City of New York Medical Department, 1891, aged 62, died, February 17, of heart disease.

Theodore L Gamblin, Burnside, Ky., Kentucky School of Medicine Louisville, 1896, aged 60, died suddenly, February 8, of heart disease.

Arthur Deane Dunn, Cashmere, W Va., Chattanooga (Tenn) Medical College, 1903, aged 70, died suddenly, January 20, of heart disease.

Samuel W Jenkins, Soddy, Tenn., Chattanooga (Tenn) Medical College, 1894, Civil War veteran, aged 84, died, January 19, of influenza.

Elias Nyman Figved, Boston Middlesex College of Medicine and Surgery, Cambridge, 1918, aged 60, died, Nov 18 1932, of heart disease.

Lincoln Morris Ernst, Harrisburg, Pa., Jefferson Medical College of Philadelphia, 1910, aged 45, died, February 5, of heart disease.

Charles F Howe, Atchison Kan., Northwestern Medical College, St Joseph, 1894, aged 72, died, Dec 25, 1932, of duodenal ulcer.

Marcellus N Brown, Cuero, Texas, Meharry Medical College Nashville, Tenn., 1893, aged 75, died, February 11, of pneumonia.

Joseph Cerny ♂ Wilber, Neb., Jenner Medical College Chicago 1899 aged 67, died, Dec 27, 1932, of carcinoma of the stomach.

C E Fuller, Morristown Tenn Medical College of Georgia Augusta 1869 Confederate veteran, aged 86, died, January 2.

Horace R Wells, Yakima, Wash University of Minnesota Medical School, Minneapolis, 1898 aged 68, died, Nov 25 1932.

Abram M Leland, Whitewater Wis Milwaukee Medical College 1900, aged 67 died suddenly, February 1, of heart disease.

Walton Haydon Marshfield Ore. (licensed, Oregon, 1893) aged 78 died Dec 15 1932 of cerebral hemorrhage.

William E Dodds, Richland, Iowa, Rush Medical College Chicago 1885 aged 77 died, February 1, of heart disease.

John H Cawood St Louis Barnes Medical College St Louis 1895 aged 65 died February 10 of carcinoma.

Bureau of Investigation

CRAZY CRYSTALS

Just One More Saline Laxative

During the past year a large number of inquiries have come to the Bureau of Investigation for information on the product known as 'Crazy Crystals,' put out by the Crazy Water Company of Mineral Wells, Texas. An Iowa physician who sent in some Crazy Crystals advertising wrote

'These people are flooding the country with letters like this and they accidentally sent one to me. I should think it would be easy to run this thing down and warn the public. What are Crazy Crystals? The middle west is riding on a wave of Crazy Crystals at present. They are wonder fully efficient in rupturing the appendix. I had one where the solution ran out of the abdomen after drainage, and re-crystallized in the sheets.'

A Better Business Bureau in the east telegraphed

'Desire information Crazy Crystals put out by Crazy Water Company, Mineral Wells, Texas. Claim to be a mineral water treatment. Appreciate information.'

A physician in the State of Washington who protested to the local Better Business Bureau against the radio broadcast-

also sold "Crazy Water Concentrated," which was said to be Crazy Water that had been evaporated to one-fifteenth of the bulk of the natural water.

The rather unusual name for the product is said to have been derived from the alleged fact that many years ago two women whose "minds were seriously affected" drank this water and "were soon restored to health and their minds became normal." Hence the well from which this water came was called Crazy Well. Later, when the thing developed commercially, there seem to have been four Crazy Waters, presumably from four different wells. According to the analyses furnished, all four contained the same ingredients, but these ingredients varied in quantity. In all of them, however, Glauber's salt (sodium sulphate) was the predominating ingredient. From the published figures, it appears that the most important ingredients of Crazy Water are, in terms of grains to each United States gallon

Sodium sulphate (Glauber's salt)	267
Sodium chloride (table salt)	24
Calcium bicarbonate	19
Magnesium bicarbonate	13
Magnesium sulphate (epsom salt)	7
Potassium chloride	5
Sodium carbonate (washing soda)	2

In the case of Crazy Water Concentrated, the main ingredients, in terms of grains to each United States gallon, are given, in round figures, thus

Sodium sulphate (Glauber's salt)	3858
Sodium chloride (table salt)	177
Calcium bicarbonate	49
Magnesium bicarbonate	49
Magnesium sulphate (epsom salt)	248
Potassium chloride	84
Sodium carbonate (washing soda)	64

It will be noted that the proportion of the epsom salt in the Crazy Water Concentrated is considerably greater than in the natural water. But whatever one accepts as the correct composition of the various Crazy Waters, it must be obvious that unless the claims for composition are wholly false, Crazy Crystals are, for all practical purposes, Glauber's salt with certain added amounts of washing soda and epsom salt common salt and other salines.

Crazy Crystals are advertised by typical "patent medicine" methods. In addition to radio talks, there are advertising leaflets of a type common to nostrum exploitation. We are told directly that Crazy Crystals have been used successfully in the treatment of

High Blood Pressure	Bad Complexion
Stomach Disorders	Excess Acidity
Auto Intoxication	Constipation
Nervous Ailments	Rheumatism
Neuritis	Diabetes
Arthritis	Liver and Bladder Troubles
Kidney Trouble	

THE CRYSTALIZER

YOU SHOULD KNOW THESE FACTS ABOUT CRAZY CRYSTALS

Among the most important facts about Crazy Crystals is that they are a natural mineral water product. They are composed of pure mineral salts and are not a drug. They are sold in a convenient form, and are used by millions of people in all parts of the world. They are a natural mineral water product, and are not a drug. They are sold in a convenient form, and are used by millions of people in all parts of the world.

PRESCRIBED BY MANY LEADING PHYSICIANS

Crazy Crystals are produced from Crazy Water at Mineral Wells, Texas. Mineral Wells water is used and prescribed by hosts of leading American physicians. Dr. J. S. Abbott, formerly chief of the United States Food and Drug Department, pronounced it the best mineral water in the world.

It is a noteworthy fact that of all the mineral waters produced and sold only two have ever passed the exacting laboratory tests to gain permission to be advertised in the physicians' national directory and the Mineral Wells water was one. Among its unusual characteristics are that it is crystal clear, odorless and of all the effective mineral waters the most palatable.

CRAZY CRYSTALS—THE BEST JOB AND HEALTH INSURANCE

It is a fact that Crazy Crystals are a natural mineral water product. They are composed of pure mineral salts and are not a drug. They are sold in a convenient form, and are used by millions of people in all parts of the world. They are a natural mineral water product, and are not a drug. They are sold in a convenient form, and are used by millions of people in all parts of the world.

CRAZY CRYSTALS

A MINERAL WATER PRODUCT

PRICE 15¢

Greatly reduced facsimile of some of the Crazy Crystals advertising leaflets

ing on Crazy Crystals, in which the stuff was described as "not a drug," wrote

"In urging people to buy and try the product [Crazy Crystals] the statement is made by radio that they are treating or curing themselves without the use of drugs." The latter statement appears to me to be somewhat misleading.

A radio station in Connecticut telegraphed

"Please send us complete information Crazy Crystals mineral water collect."

A Better Business Bureau wrote

"We have been advised that in recent advertising over the radio of the above product, it has been stated that the product is not a drug, but a mineral water. I assume that the statement that it is a mineral water is probably true. However, I question the statement that the product is not a drug. You are familiar with the composition of the product, as represented by the company, so I wonder if you can advise me whether or not the preparation would be regarded as a drug."

According to the advertising, Crazy Crystals are nothing more mysterious than the mineral constituents evaporated "from the mineral waters found at Mineral Wells, Texas, and Thorndale, Texas." While Crazy Crystals have been on the market for more than sixteen years, it is only within the past year that an aggressive and blatant advertising campaign has been carried on. In the earlier days the product that was most advertised was Crazy Water, although there was

Indirectly, by the testimonial route—and of course there are any number of testimonials—the product is alleged to have been a Godsend in a number of other conditions, such as "stricture of the bladder," piles, dilatation of the heart, etc. Much is made of an alleged testimonial credited to "Dr. J. S. Abbott, former chief of the United States Food and Drug Department," who is alleged to have pronounced Crazy Water "the best mineral water in the world." In some of the very old advertising of Crazy Water (not Crazy Crystals) there was published a testimonial from that professional testimonial-giver, W. H. Morse of Hartford, Conn., whose name appears on testimonials for more fakes than any other individual listed in the Bureau of Investigation's files.

Crazy Mineral Water (not Crazy Crystals) has been the subject of action on the part of the federal food officials in a number of cases. Sixteen Notices of Judgment have been published, between April 1913 and October 1928 declaring Crazy Mineral Water misbranded. Fourteen of the sixteen cases involved, not simple misbranding, but adulteration, charging that the specimens seized contained filthy, decomposed and putrid substances. The last two cases charged misbranding because of the false and fraudulent curative claims on the bottle labels—claims that might have led the public to believe that Crazy Water was curative in rheumatism, functional stomach diseases, cystitis, diabetes, Bright's disease, etc.

It is worthy of note that although the courts have declared that certain therapeutic claims that used to be made on the label for Crazy Water were false and fraudulent, the company still makes similar claims today, but is shrewd enough to confine them to the general advertising matter that cannot be reached under the National Food and Drugs Act. The incident is characteristic of "patent medicine" exploitation. The shrewd nostrum exploiter of today says less and less on the trade package which brings it within the purview of the National Food and Drugs Act, but about as much as ever in the newspaper advertisements, circulars and radio talks which, while technically subject to the penalties of the fraudulent advertising laws of the forty-eight states, are practically exempt from the operation of these laws because the laws themselves are seldom if ever enforced.

Summed up, it may be said that the dollar-and-a-half package of Crazy Crystals will accomplish nothing that cannot be accomplished equally well with a few cents' worth of Glauber's salt. The attempt, in the radio advertising of Crazy Crystals, to make the public believe that the preparation is not a drug is simply playing tricks with the English language. The Crazy Crystals product is just as much a drug as Glauber's salt, epsom salt or any other saline laxative sold for the treatment of human ailments.

Correspondence

"MATERNITY WARDS IN GENERAL HOSPITALS" REPLY TO DRS SKEEL AND RUNNELS

To the Editor—I am gratified to learn that the Cleveland Hospital Obstetric Society (*THE JOURNAL*, February 25, p 597) agrees with me on the main issue. "Actual physical separation and entirely separate personnel are essential to safety. Isolated separate labor and delivery rooms are necessary. The laundry of the maternity division should never be mixed with that of the medical and surgical floors, so that sheets, pillow cases, and the like that have been used by infected surgical patients cannot be sent from the laundry to the obstetric floor. No hospital has the moral right, and none should have the legal right, to accept cases for delivery without making physical and administrative preparation for their safe care. What more do I ask than this perfect separation?" I will concede that if the maternity ward of the general hospital were on a completely separated floor and that if the doctors, students, nurses, orderlies, laundrymen and maids always carried out an intelligent aseptic technique the equivalent of that practiced in the best surgical operating rooms, while even then it would not be possible to insist it is perfectly safe to treat maternity cases under the same roof with surgical and medical cases the element of danger would be reduced to such a minimum that the public would be willing to accept it against the expense and trouble of carrying out ideals.

The requirements respecting isolation of the maternity ward, of Drs Skeel and Runnels are even more exacting than those I set and I know from much painful experience that the vast majority of general hospitals do not—and cannot—carry them out. It proves to be humanly impossible as I showed in my paper. Therefore I ask for the complete architectural and administrative separation of the two services.

I must disagree with the statement that my argument is based on the ratio of epidemics in the two kinds of hospitals. The conclusions were based on the results of a study of the situation as it exists in many countries and particularly on my own personal experience in the hospitals of Chicago in my private practice and consultation practice and in the practice of an inner city emergency outpatient service.

I am fully aware that the septic mortality in any country is probably half due to criminal abortion, but in the

epidemics mentioned these were not included, and in the few times the general septic mortality was referred to it was to show that, in spite of hospitalization of an increasing number of confinements, the mortality kept up. Sigwart is quoted on this point. Further, not the cases of infection brought to a hospital are considered, but only those developing in the wards.

I regret that I did not make myself clear on the relative importance of air-borne and indirect contact infection. I cannot state my opinion any better than in the three different sentences I devoted to this particular point, and for which I respectfully ask reconsideration.

The single object of the paper, was again to call attention to the danger that lurks in general hospitals for the maternity case and to urge that an ideal be set up for which all may work.

J B DELEE, M D, Chicago

SUBOCCIPITAL MENINGOCELE

To the Editor—In *THE JOURNAL*, January 28, is published a report by Dr O H Fulcher of the removal of a suboccipital meningocele. Concluding his report, Dr Fulcher says "Suboccipital meningocele is a condition that is rare. Usually the treatment has been quite unsatisfactory. This is the first case, to my knowledge, that a suboccipital meningocele has been successfully treated by a one-stage operation."

In September, 1928, while in the Iowa University hospital, I operated on a railroad employee from Davenport, Iowa, who was 40 years old and who had a suboccipital meningocele the size of the patient's fist. This was a one stage operation and a cure was accomplished. In 1929, in the same university hospital, I operated on a child, 2 months old, from Sioux City, with an enormous suboccipital meningocele, which was the size of the child's head. The same child also had a lumbar spina bifida. The suboccipital meningocele was successfully treated by a one-stage operation and the child is at present 4 years old and well.

ANATOLE KOLODNY, M D, Sioux City, Iowa

REVIEW OF CUSHING'S "INTRACRANIAL TUMORS"

To the Editor—Among the things that I particularly admire about *THE JOURNAL* are the excellent critical reviews of books. Rarely are they inadequate and seldom unjustly critical, and I have almost never seen a stupid review. I cannot refrain from making some comment on the astonishing paragraph you have just published concerning Dr Cushing's monograph on intracranial tumors (*THE JOURNAL*, January 28, p 284). In drawing your attention to it, I do so fully realizing that as a student of Cushing I may be a prejudiced critic.

Quite apart from the spirit of the review, I shall only protest against the errors of statement. Beginning with his fourth sentence the reviewer says that Cushing's mortality rate remained fairly constant until 1930 and that it then dropped for no adequate reason. The whole point of the book is thus missed for had the reviewer but glanced at the tables, especially those on pages 142 and 143, he would have seen that there has been a steadily progressive drop in the mortality rate since 1912 and furthermore, that Dr Cushing has been at pains to give an entirely adequate explanation of the remarkable drop that has occurred since 1928 (not 1930, as stated by your careless reviewer). I should like to know what the reviewer means by the phrase "trephining through biopsies." All operations on the cerebral hemispheres have involved the reflection of a bone-flap and any one who is even remotely familiar with the technique of Dr Cushing's school could not possibly have referred to biopsies trephining. It is a type of ignorance that would be understandable from neurologic surgeons of the prewar period but it is incomprehensible as coming from the pen of any one on this side of the water at the present time.

Finally, one observes in the next to the last statement the phrase "Also the tables give no information except as to life" What the reviewer could have had in mind would be impossible to imagine, for Dr. Cushing is careful to state that his report has to do with his surgical mortality statistics and the various pathologic types of brain tumor, and that he proposes to give no details concerning ultimate expectation of life, since this has already been adequately dealt with in his report with Bailey.

J F FULTON, M D, New Haven, Conn

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted on request.

DIAGNOSIS AND TREATMENT OF MULTIPLE STONES IN COMMON DUCT

To the Editor—I have a patient aged 27, who with a past history of typhoid eight years ago, and pregnancy with twins two years ago has had daily attacks of sharp epigastric pain radiating round the body at this level coming on about two hours after each meal, for the past one and a half years. Physical examination, roentgenograms of the gastro-intestinal tract, gallbladder and kidneys, and all laboratory tests gave apparently normal results. Nothing relieved the pain except an opiate. A diagnosis of chronic gallbladder disease was made by elimination and at operation in June of this year a small, apparently normal gallbladder was removed together with twenty small millet seed stones which were found closely packed into the mouth of the cystic duct. There were no stones in the common duct and a normal appendix was removed at the same time. There had been no jaundice and gallbladder bile had been aspirated with the duodenal tube on several occasions previously. The patient made an excellent recovery and felt perfectly well for about two months. Now for the past two months she has had similar attacks of sharp agonizing pain in the epigastrium, this time without radiation and coming on from half an hour to an hour after her noon and evening meals only. The pain is very intense and is relieved only by morphine. Diet seems to have no part in the picture, since she will have an attack following nothing more than a glass of milk. There is no vomiting or diarrhea with these attacks, but a very marked degree of flatulence and belching of gas. There is no tenderness or spasm in the abdomen, in fact physical examination is entirely negative except for a hemoglobin of 60 per cent. There is no jaundice, the stools are always dark, no stones are found in the feces, and chemical examination of the blood and repeated roentgenograms are normal. The blood cholesterol before operation was 190 following operation 140. I am greatly concerned about this patient and anything you may be able to offer in the way of diagnosis, further study or treatment would be greatly appreciated. If there are any other questions you may have in mind about further history or examination, kindly use enclosed self-addressed envelop at your earliest convenience. Please omit name.

M D, New York

ANSWER—When a surgeon removes a gallbladder containing stones he can never say with certainty that no stone is left in the common duct. This statement applies with particular emphasis when the stones are small, especially the size of millet seed. Two well recognized facts emphasize this assertion.

1 Digital palpation of the unopened common duct and ampulla is an unsatisfactory method of examination, because stones several times the size of the ampulla may be overlooked.

2 Such stones may even be overlooked when the duct is explored by probe and scoop, because they lie high in the hepatic duct or may even be intrahepatic. Later they are washed down and produce colic and obstruction. The post-operative course of this patient makes it practically certain that she is suffering from one or more common duct stones. The absence of jaundice or of stones in the stools does not eliminate this condition. A van den Bergh test on the blood during the height of the attack, or the examination of several urine specimens for bile some two to six hours after, will often be confirmatory of delayed drainage, if not of obstruction. Such fine stones often pass the ampulla, and sufficient time should be allowed for this to occur. The surgeon must be guided by the intensity and frequency of the attacks as to how long he will wait. It is not uncommon for such attacks to occur for months or even several years after operation and then, decreasing in frequency, finally disappear. A so-called gallbladder diet is advisable but offers no assurance against attacks, as this case demonstrates. If life becomes untenable because of severe and frequently repeated attacks, or if jaundice occurs, the duct must be explored. It must be emphasized that the appearance of jaundice in such a patient, particularly

if persistent, is far more serious than in one who has a gallbladder. Exploration of the common duct under such conditions, i. e., the absence of a gallbladder, requires consummate skill and deliberation. The duct must be repeatedly explored with as large a scoop as can be passed into the duodenum, by way of the ampulla, and the hepatic duct should be flushed out with physiologic solution of sodium chloride by means of a cannula, in order to dislodge any stones not reached by the scoop. Tube drainage of the duct for ten days or so is advisable.

SURGICAL TREATMENT OF SPASTIC COLON—HIRSCHSPRUNG'S DISEASE—CUTTING PELVIC NERVE

To the Editor—1 Is there any kind of operation for a spastic colon? 2 In Hirschsprung's disease sympathectomy is done. Would this operation help a spastic colon? 3 Is there any deleterious after-effect from cutting the pelvic nerve? Please omit name.

M D, Pennsylvania

ANSWER—1 Exploratory laparotomy, appendicostomy for the purpose of irrigation, partial and total colectomy, and ileosigmoidostomy have been performed in the treatment of spastic colitis. It is the opinion of medical authorities, however, that "such surgical procedures for the treatment of this condition are unnecessary, unjustifiable and cannot be too strongly condemned (Barker, L. F. The Spastic Colon and Mucous Colopathy, *Am J M Sc* 178 606 [Nov] 1929; Friedenwald, J., Feldman, M., and Rosenthal, L. J. Mucous Colitis, *Ann Int Med* 3 521 [Dec] 1929).

2 The sympathetic fibers to the colon carry mainly impulses which depress motility and inhibit tonus. Sympathectomy of the type performed for Hirschsprung's disease would probably be of no value in spastic colitis, since the motility and tonus would be increased in a bowel already hyperkinetic and with disturbances of coordination.

3 Cutting of the pelvic or, as it is now termed, presacral nerve may result in vesical and rectal damage of varying degree. The deleterious effects produced are chiefly:

(a) Loss of ejaculatory power in men; the reproductive function in women is not affected by this operation.

(b) Diminution of tone of the internal sphincter of the rectum, part of which is recovered within several weeks.

(c) Flaccidity or decrease of motor power of the trigon of the bladder, with resulting residual accumulation of small quantities of urine.

TREATMENT OF HYPERTENSION

To the Editor—Can you give me suggestions for the treatment of hypertension? Systolic pressure varies from 200 to 230 and better, and diastolic about 80 points lower, following the systolic in its variations. The patient, a woman, aged about 55, has a valvular cardiac disorder of about twenty years standing. There is not much edema of the feet, and she has learned to control that with digitalis. Roentgenograms show only slight cardiac enlargement. Examination of the urine shows 4+ albumin, but there are no casts and it is otherwise negative. There is a tendency to overeating, she weighs about 180 pounds (80 Kg). A reduction of diet and a lowering of pressure by means of thioacetamide causes weakness with more marked shortness of breath and like symptoms. She feels better when the pressure is high and she is carrying on with house work. How great is the danger of letting the high pressure continue? What do you think of the value of Viscyte (Bischoff)? I would appreciate any other suggestions. Chemical examinations of the blood, made several times, give negative results. Rest in bed lowers the pressure very little and brings on more weakness. Please omit name and address.

M D, Alabama

ANSWER—In every instance of hypertension, a working knowledge of the degree or absence of renal insufficiency is of paramount importance. While not giving information of a precise nature, the phenolsulphonphthalein excretion test (in a case not showing manifest hepatic insufficiency), together with the concentration and dilution test, is of distinct value, especially when there are no chemical changes in the blood. An ophthalmoscopic examination is indicated, for, by virtue of the degree of retinal arteriosclerosis and presence or absence of hemorrhages and exudates, one may obtain an index of the degree of cerebral arteriosclerosis. The clinical history and examination point to an associated generalized arteriosclerosis with renal arteriosclerosis or nephrosclerosis and cardiac decompensation. The cause of this marked albuminuria needs to be explained, for benign nephrosclerosis with such a mild degree of cardiac failure usually is not sufficient. One must consider a nephrosclerosis now in the malignant phase or a chronic mixed nephritis with the nephrotic component predominating. Repeated examinations of fresh specimens of urine are indicated because casts disintegrate in urine of low specific gravity or low sodium chloride content, or if alkaline,

and because red cells become hemolyzed in urines low in sodium chloride. In view of the marked proteinuria, the blood plasma albumin, globulin and cholesterol should be determined. Edema may be anticipated if the albumin falls below 23 per cent, whereas a high cholesterol fraction points to a nephrotic component. The danger from such continued high blood pressure is wholly dependent on the integrity of the myocardium and of the cerebral vascular tree. Further studies of the renal function are of prognostic importance. The diet should contain bland simple foods and from 150 to 175 Gm of protein daily. Restricted activity with from one to two hours of complete rest after each meal is to be advocated for an indefinite period, depending on the degree of improvement, and mental and physical relaxation is to be practiced. A mixture of sodium bromide, 0.65 Gm (10 grains), and potassium iodide, 0.3 Gm (5 grains) three times daily, may be tried. Like many other vasodilators, Viscyte may not be expected to be of much if of any value in instances such as this.

X-RAY TELANGIECTASIA

To the Editor—A woman aged 31 is in good general health. Eleven years ago she had symptoms of thyroid hyperactivity and following a course of medical observation and treatment in a hospital she consented to an operation. An almost vertical incision was made and the patient believes that only a ligation of blood vessels was done and that none of the gland was removed. She was then advised to undergo roentgen therapy at the same hospital. She received between fifteen and twenty treatments at bimonthly intervals. She soon noticed hoarseness. Four or five years following the roentgen therapy she noticed a few capillary enlargements in the skin vessels of the neck. These have gradually increased in size and in number until at present the entire anterior surface of the neck and suprasternal region shows a bluish mottling with prominent dilated capillaries. There are no keratotic areas. She is worried mostly on account of the cosmetic defect of the vertical scar and the appearance of the skin of the neck. How much further cosmetic damage may be expected locally and how much damage to her general health? What is the likelihood of a carcinoma developing? Can anything be done to improve the appearance of the skin? From the medico-legal point of view is the hospital liable? Kindly omit name.

M D New York.

ANSWER—The condition mentioned is telangiectasia which is a well known sequela to roentgen and radium treatment. The telangiectasia has probably reached maximum development. It usually persists for many years and may be permanent.

In some instances the telangiectasia improves and disappears in time. If there is no atrophy or sclerosis present now these conditions may not and probably will not develop in the future.

It is possible but unlikely that keratoses and ulcers may develop in the future and it is even possible that cancer may occur. If so the epithelioma will be preceded by either an ulcer or a keratosis.

The laws differ in the various states. A charitable institution is usually exempt but the physician who gave the treatment or the head of the department is often held responsible. In the case of a private patient it is usual for the physician who had charge of the patient to be held responsible.

The appearance can be improved by expertly applied electrolysis but such treatment is tedious and time consuming and therefore expensive. It also requires perseverance. Ultraviolet radiation if judiciously applied often gives good results. On the whole treatment for large areas of intense x-ray telangiectasia is not especially satisfactory.

TOLERANCE FOR POTASSIUM COMPOUNDS

To the Editor—I have a patient who has sufficient myocardial degeneration to give him edema and ascites. The kidneys show no damage. Since reading the article in *THE JOURNAL* about the influence of sodium and potassium on edema I have treated this patient accordingly. I have had to increase the potassium to 75 Gm a day. Now I am rather anxious to know how much potassium in the form of salts can be given without danger and also whether there is any way to tell the urine for the amount of potassium excreted. I have access to the university chemistry department and therefore have all the facilities necessary for the examination. The only method of examination that I know involves the use of platinum and the cost is prohibitive to the patient. I shall greatly appreciate the information. Please omit name.

M D New Jersey

ANSWER—No definite statement can be made that will cover individual potassium tolerance and its toxicity has not been well investigated. Large doses of various forms of potassium have been administered and reported. Blum, Aubel and Levy (*Chimie et Industrie Médicale Paris* 45:150, [Nov 18] 1921) gave sodium chloride and doses of 10 Gm daily and

that the limits are from 75 to 25 Gm a day and that they desired to increase the dose but that these salts were not well tolerated in amounts above 25 Gm because of diarrhea and circulatory damage. Wilks (*Guy's Hosp Rep* 9:173, 1863) gave potassium nitrate, 18 Gm daily, in renal dropsy with "satisfactory results." Addison (*Canad M A J* 18:281 [March] 1928) reports giving 8 Gm of potassium citrate, from 6 to 8 Gm of potassium bromide or from 6 to 8 Gm of potassium chloride over considerable periods of time and recommends their use. Bunge states that in some cases the food contains from 50 to 100 Gm of potassium daily without showing toxicity. Osman (*Guy's Hosp Rep* 77:386 [July-Oct.] 1927) gives large doses of potassium citrate in cases of renal edema. He gave 32 Gm to a child weighing 20 Kg daily in combination with sodium bicarbonate. He gave 38 Gm to a child aged 14 until the edema was reduced and then maintained the dosage at 24 Gm daily. Osman gave 66 Gm of potassium citrate to a man aged 23. No clear statements of serious effects were recorded, even though large doses of various potassium salts were given.

The quantitative determination of potassium in the urine is quite simple and accurate by the method of Breh and Gaebler for serum potassium (*J Biol Chem* 87:81 [May] 1930). Urinary albumin, if present, is removed by acidifying and boiling, the ammonia is removed by boiling with sodium carbonate, and the chlorides are precipitated with silver nitrate. The urine is then diluted and filtered. Enough of the filtrate to contain 0.2 mg of potassium is then used for the potassium reagent. Of course, the amount of potassium excreted varies with the diet and medication and it may require a little practice to judge the amount of filtrate to use.

ARTHROPATHIA PSORIATICA

To the Editor—I have encountered an interesting case that I have not been able to explain, namely, the presence of a complication to psoriasis—a general arthritic manifestation. The patient is a woman aged 40 who gives the following history. No familial tendency to psoriasis has been observed. Eight brothers and sisters are well. At the age of 13 a slight psoriasis of the flexor surfaces of the elbows and knees developed. Menstruation began at 18 not characterized by symptoms the periods lasting only one day and the amount of flow being very slight. The patient married at 19 and has had two children the birth of whom was characterized only by slight pyelitis for two weeks after delivery. There was no skin manifestation during pregnancy. Remissions of psoriasis occurred for periods of three or four years with return of the skin lesions. Menstruation ceased at 37. The patient indulged in a high protein high spicy diet last summer and a marked increase in the spread of the skin lesion developed being universal except for the face and the palms of the hands. Five weeks ago a marked universal stiffening arthritis developed with swelling of the joint areas associated with severe pain on motion. Every joint in the body has been involved and been very painful. There has been marked swelling of the ankles and feet. The systolic blood pressure is 112 diastolic 60. The temperature is normal. The urine is normal except for a trace of albumin. Treatment for a period of four weeks has been as follows: (a) nonprotein diet with complete removal of all proteins; (b) white petrolatum to the skin; (c) three intravenous injections of ampules of choline salicylates and iodides weekly; (d) moniodocinchophen anodupyrine by mouth; (e) catharsis. At present the patient shows marked improvement except for slight joint pains and edema of the ankles. Her skin is markedly improved and appears normal except for redness where her lesions have existed. I am interested in knowing the cause and prevalence of arthritic manifestations in psoriasis or whether in this case there exists an associated arthritic condition. What is the recognized treatment of the condition described? Is there an associated endocrine disturbance (ovarian here) to account for her condition? Would endocrine therapy be useful? I should appreciate being enlightened concerning this case.

JACOB GOLDBERG M D Long Branch, N J

ANSWER—A condition known as arthropathia psoriatica has been described in the literature. Arthritis and psoriasis apparently may be combined in two ways. Small scattered patches of psoriasis are not infrequently seen in patients with chronic infectious arthritis the two diseases apparently being independent. True psoriatic arthritis however seems to be the result of long continued uncontrolled psoriasis and usually comes on months or years after the onset of the skin disease. Some investigators have made an effort to determine a specific type of arthritis but it would seem from the reports that such a differentiation is difficult. Not all of the authors are in agreement as to what the peculiarities of this specific arthritis are.

The treatment should be directed toward cure of the arthritis as well as toward the psoriasis. The treatment given in this particular case seems to have been well rounded and logical. A warning should be issued about cinchophens because of the recent reports of fatal hepatitis following the use of this drug.

This patient also seems to show disturbances of the endocrine system in the history of late menstruation and early menopause, and for that reason hypodermic ovarian therapy, with perhaps small doses of thyroid by mouth, might be of value.

One other point in the history, namely, the story of postpartum pnelitis, brings up the question of possible focal infection. It is strongly advised that any focus of infection that this patient may exhibit should be eliminated.

Arthropathia psoriatica has been described in the following articles:

- Scholl, O. K. A Case of Psoriasis Arthropathica Complicated by Acrodermatitis Atrophicans. *Dermat. W'chenschr.* 81: 1223 (Aug. 22) 1925.

BLOOD COAGULATION AFTER DEATH

To the Editor—During a recent examination after the death of a patient from a coronary occlusion, a phenomenon occurred that seems to be unusual. When the blood (about 30 cc) was taken, it was found to be without clotting properties. The calcium content was 14, and, when whole blood of known normal clotting time of the same type was added, a clot formed which dissolved in about five minutes (equal parts of the two samples of blood were used). The addition of calcium salts did not produce clotting. The patient who had been in good health previously, died suddenly unattended. For my personal information, I should like to know the following: Does this occur normally as a postmortem change? (I have not seen it in about 800 cases.) In what types of poisoning (other than phosphorus or chloroform) may this phenomenon be present and how could one determine the presence of these substances? Could you suggest a possible cause other than the causes mentioned, for such a phenomenon? The platelet count (post mortem) was 56,000. The complete postmortem examination showed nothing pathologic except the small plug in the middle third of the right coronary artery. Please omit name and address.

M D

ANSWER—These are difficult questions to answer satisfactorily. Nothing is said to indicate whether or not any clotting of the blood had taken place spontaneously after death or whether the body had been injected with preserving fluid. It is possible that clotting may have taken place in the usual way after death and that the blood which was found to be "without clotting properties" simply represented serum and blood corpuscles that had been squeezed out of the clot. That the clot which formed on the addition of whole blood dissolved in about five minutes is a curious phenomenon. The only explanation one can offer would seem to be that some factor was present which neutralized or removed the antitryptic properties of the blood. The platelet count of 56,000 after death cannot be regarded as of any significance in indicating the number of platelets present during life.

RECURRENT ERYSIPELAS INFECTION OF LEG

To the Editor—A girl, aged 15 years, for the past five years has suffered from attacks of an acute, habitually recurrent, erysipeloid infection of the right leg. I do not believe that it is a true erysipelas or exactly a lymphangitis, although it resembles both closely and causes great local distress and general prostration during an attack. Attacks recur at intervals of from three to six weeks and the temperature rises to from 102 to 104 F for two to four days, after which it quickly subsides and she passes to comparative ease and comfort. The leg for the past two years has remained swollen between attacks. I have been unable to influence the frequency or severity of these attacks. I have tried all the usual textbook local applications and fever mixtures, with opiates for pain. Between spells she has been given a series of small doses of erysipelas antiserum, a course of mixed streptococcus vaccine, and foreign proteins. After the removal of only slightly diseased tonsils an autogenous vaccine was made and used. No other foci of infection have been located. Any suggestions as to further treatment would be greatly appreciated. Would roentgenograms be of any value?

W R MEEKER, M D, Mobile, Ala

ANSWER—So-called recurring erysipelas of the leg is thought by some to belong in the category of cellulitis. It is unusual for recurring attacks to take place at such frequent intervals and with such a marked constitutional reaction. A persistent solid edema of the affected parts is the usual sequel of the infection. Since Birkhaug introduced the antitoxin treatment of erysipelas in 1926 there have been a number of reports on its use in recurring cases. Symmers showed in a series of 705 cases that the intramuscular injections of the concentrated antitoxin in 10 cc doses does not confer immunity or prevent recurrent attacks, its value lying solely in its ability to control the immediate attack and shorten the duration of the disease.

Birkhaug treated sixty-eight cases of recurring erysipelas with gradually increasing doses of streptococcus toxin alone or a mixture of erysipelas toxin with killed streptococcus. The initial dose was 0.1 cc intramuscularly and was gradually increased every ten days to a maximum of 3 cc. In six cases an erysipelas-like eruption was observed along the route of the relapsing attack with a febrile reaction. In the others, apparent immunization against recurring attacks was brought about. Amoss has treated successfully twenty-three cases of recurring erysipelas of the leg. He found that the skin of the affected leg reacted more intensively to the endodermal injection of 0.1 cc of streptococcus filtrate than the skin of the other leg or arm. Treatment was begun with subcutaneous injections of increasing doses of 0.1 cc of 1:100 dilution of the filtrate from the strain that gave the greatest reaction. Every five days the dose was doubled and then continued with 1:10 dilution and finally the undiluted filtrate. Amoss also emphasizes the importance of searching for breaks in the skin between the toes and in every case found a fungal infection of one or both feet (epidermophytosis) and in a few cases was able to grow hemolytic streptococci from the debris round the edge of the toe nails. The following treatment of the toes is advised: At night a Whitfield ointment fortified with 1 per cent thymol iodide is applied. In the morning the toes are cleansed with soap and water and wiped with 70 per cent alcohol, and 1 per cent solution of thymol iodide in 70 per cent alcohol is applied. During the day a dusting powder is used containing salicylic acid 5 parts, thymol iodide 1 part, boric acid 50 parts and starch 50 parts. With proper treatment of the feet it is possible that immunization may not be necessary.

Roentgenograms would be of questionable value.

SENILITY WITH PAROXYSMAL TACHYCARDIA AND FIBRILLATION

To the Editor—A man, aged 75, had a lifetime of robust health excepting for two or three annual attacks of acidosis with diarrhea since youth, which stopped five years ago. The vital organs are normal excepting for functional heart disturbance, which began a year ago. The arteries are soft. The blood pressure averages 145 systolic, 75 diastolic. The average pulse is 64. Motile spermatozoa were found when the vesicles were massaged in search of infection. The appetite has never failed "everything is eaten" excepting when the patient is on a diet. He has eight hours of restful sleep nightly. He has had one bowel movement after breakfast for years. He is a moderate user of alcohol and tobacco. There is no history of venereal disease. He comes from a long lived family in which there have not been neuroses or psychoses. A careful search was made for infections. None were found in the tonsils or gallbladder. Streptococcus viridans was obtained from a tooth root and eliminated. Many customary colon bacteria were found but cultures indicate that no one in particular is a sensitization factor. Nevertheless considerable colonic fermentation and putrefaction has existed for a year. Intestinal antiseptics seem to control all but the gas formation. A year ago occasional heart flutter appeared at times. Tachycardia is transitory. Bradycardia occurs for short periods far apart. Competent consultants have been seen. Cardiograms show normal action much of the time. At other times there is fibrillation, the irregularity of heart action progressive and increasing. Experts are not agreed on a maintenance dose of digitalis, the drug seems to be poisonous at times. Small doses of quinidine have proved helpful. A vegetarian diet is helpful, cured meats and fish being allowed. Recently distressing polyuria has occurred occasionally, lasting a few hours. Limpid urine in great quantity is passed every twenty minutes, then the condition stops as suddenly as it begins. Profuse perspiration has a weakening effect at times. The patient feels hot, with cold perspiration and a normal temperature. Rest periods of longer and longer duration have been taken. The patient now spends most of the day on a couch. He is failing day by day. Periods of good days and bad days have alternated from the first. What is the matter with him? Please omit name.

M D, New York

ANSWER—The story suggests senility, associated with the usual arteriosclerosis, especially involving the cardiac and mesenteric vessels. If the basal metabolic rate has not been determined, it should be, in order to rule out the thyroid as a cause for the paroxysmal tachycardia and fibrillation. To control the colonic fermentation and putrefaction, a change of the intestinal flora to the aciduric type would be advisable. This can be accomplished by the use of acidophilus milk. If necessary, lactose may be added to the diet. Empirically, iodides should be given as an alternative.

CHEMICAL IRRITATION FROM FUMES AND VAPORS IN OXYACETYLENE WELDING

To the Editor—A man aged 43 suffers a pustular chemical dermatitis of the lips chin nose and nostrils with extensive cellulitis following exposure to fumes arising from an oxyacetylene welding process. The process said to be responsible was as follows: Two old metal plates assumed to have been galvanized, each 14 inches wide and one-fourth inch thick, were to be welded by an oxyacetylene torch. The operator had been at the work only two days but wore a respirator and goggles. It was necessary for him to keep his face close to the work. Chemical analysis of a sample of the metal showed the presence of phosphorus sulphur and manganese as well as iron and carbon. Would the fumes of oxidation from the heat of the torch give rise to the dermatitis mentioned especially the fumes of sulphur and phosphorus as ordinarily present in galvanized iron and would the fumes or manganese give rise to nausea and subsequent weakness?

A D LAZENBY M D Baltimore

ANSWER—No warrant exists for the association of this condition with any one dangerous agent in the mixture of several that attend oxyacetylene welding work. Nonetheless, much justification exists for classing the condition as the result of "mixed intoxication."

Commercial acetylene gas may contain hydrogen arsenide ("arsine"), hydrogen phosphide ("phosphine") and sulphur compounds. Incomplete combustion may give rise to carbon monoxide. The galvanized coating, assumed to have been present, paves the way for zinc poisoning, which is a frequent result of torch work on galvanized surfaces. Zinc poisoning alone would account for the greater number of happenings described in this case, particularly the "weakness," which always follows acute zinc poisoning. Metal fumes are known to be irritating to the eyes and mucous membranes of the nasal passages. The zinc oxide, which is likely to make up the greater portion of the fumes, may lead to slow mechanical action under the mask worn for protection.

The combination of chemical irritation from mixed fumes and vapors, together with some extent of mechanical irritation, both followed by bacterial invasion, provides a reasonable explanation for the "pustular dermatitis" with "extensive cellulitis."

DÖDERLEIN BACILLI IN VAGINAL SMEARS

To the Editor—In making microscopic examinations of leukorrheal discharges especially in girls and young women I frequently find in smears long chains of very large bacilli. Stained with methylene blue these bacilli are dark. They are much larger than other bacteria which usually occur in the same smear with them. The proportion of their length to their width is about that of half a match stick. Their ends are square cut and they usually appear in long chains. What are these bacilli and what is their significance if any? Please omit name and address.

M D Georgia

ANSWER—The organisms described correspond to the bacilli of Döderlein, which are normally found in the vagina in association with desquamated squamous epithelial cells. They are long straight rods gram positive, nonmotile and anaerobic. They are responsible for the acid content of the vagina by the elaboration of lactic acid and thereby act to protect the vagina against the invasion of pathogenic organisms. Döderlein bacilli may be absent in the smear during an acute infection (i. e., gonorrhea), and the return of these long rods and squamous epithelium in the smear picture during the course of treatment is looked on with favorable significance.

SYNOVIAL CYST OF WRIST

To the Editor—I have a case in which a cyst appeared over the carpal bones on the dorsum of the wrist. It was removed surgically through a skin incision and contained thick gelatinous material. It recurred within ten days as large as ever was again evacuated through a needle. It recurred within ten days and was evacuated again with a needle. Please advise the best method to prevent recurrence without making another incision. Does this cyst originate down between the carpal bones? Will several evacuations through a needle cure the condition? I had in mind injecting a few drops of phenol through the needle to obliterate the tract or using the cauterizing effect of a small diathermy electrode for the same purpose. I have never seen one quite so stubborn as this one is. I would appreciate an immediate reply giving suggestions if convenient as I want to treat the patient again as soon as possible. Please omit name when published.

M D Oklahoma

ANSWER—The successful treatment of the condition described depends on a careful excision of the entire cyst and this is sometimes a rather difficult operation because the slender stalk of the cyst must be followed through the extensor tendons to the synovial lining of the joint from which it arises. Although the cysts occasionally represent a protrusion of the synovial lining of the tendon sheath of the extensor tendons at the wrist they more often arise from the synovial lining of one of the joint spaces between the carpal bones.

It is essential in such cases to secure a bloodless field with the aid of a constrictor or a blood pressure band inflated to about 240 mm. Only when there is a bloodless field can one follow the stalk of the cyst to its origin and be certain that a complete excision has been performed.

Evacuations through a needle and injection of cauterizing agents have never been successful, in our observation, as a means of eradicating the cyst. The use of a cauterizing electric current seems distinctly contraindicated because of the danger of leaving an open wound through which infection might spread into the surrounding tissues, with unpleasant and serious consequences.

CEREBRAL GUMMA

To the Editor—A man, now 23 years of age, had chancre at 16. At that time he saw a physician who gave him some local application and the chancre disappeared. When he was 20 he started to have convulsions at night at first infrequently and then more frequently until he had them about once a week. I saw him in October 1930 did Wassermann and Kahn tests and found them to be both four plus. I roentgenographed the skull and found definite local erosion of bone in the parietal area suggesting cerebral gumma. I have treated the patient continuously for the past two years giving iodides by mouth mercurial injections and either bismuth arsphenamine sulphate or sulpharsphenamine intramuscularly. Despite the dangers of the latter the convulsions ceased and the bone erosion disappeared but the Wassermann and Kahn tests remained four plus. The eyegrounds and the perimetric field examination gave normal results. Three months ago I gave 0.15 Gm. of neoarsphenamine intravenously. Three days later the patient had a convulsion which was due probably to hemorrhagic encephalitis induced by neoarsphenamine. Since then the convulsions have recurred about twice a month despite the return to bismuth and iodide therapy. Please omit name.

M D New Jersey

ANSWER—Epileptiform convulsions from the pressure of a gumma on a motor area may lead to an erroneous diagnosis of epilepsy. Syphilitic disease of the bones of the cranium may occur as periostitis, osteitis or a gummatous formation. Exostosis and necrosis occurring side by side are characteristic. The diagnosis of cerebral gumma in this case seems well established. The absence of mental symptoms speaks against the diagnosis of dementia paralytica. Treatment has been along established lines. The flare up after a small dose of neoarsphenamine intravenously may be interpreted as a Herxheimer reaction rather than a hemorrhagic encephalitis, which is usually fatal. A course of iodobismutol intramuscularly might be tried. Fever therapy, particularly malaria, or as a substitute intravenous typhoid vaccine or hyperthermia induced by diathermy might also prove efficacious. Large doses of iodides are indicated. Tryparsamide might be tried if other methods fail.

LOSS OF LIBIDO IN WOMAN OF FIFTY SEVEN

To the Editor—A woman aged 57 married has a history of the removal of both tubes one ovary and a portion of the other ovary fifteen years ago. Eight years ago roentgen and radium treatments for a tumor of the uterus presumably a fibroid were given. Since the roentgen and radium treatments she has not menstruated (menstruation was normal before) she has had vasomotor symptoms the finger tips are blue there is shortness of breath on exertion nervousness is present and loss of libido is complete. Examination of the heart lungs blood pressure and urine give normal results. The hemoglobin (Sahli) is 75 per cent. She is somewhat masculine in type her weight is normal. How can I treat this patient to bring back the libido? Would theelin be of value? Please omit name.

M D New York

ANSWER—The chances of a woman of 57 who has only a portion of one ovary left, the function of which has probably been destroyed by the roentgen treatment, of regaining her libido are indeed slight. The only preparation that can have any effect is corpus luteum but in her condition the blood pressure must be carefully watched during its administration. Psychic treatment may also have a good result.

STRAIGHTENING KINKY HAIR

To the Editor—Any information you may give for straightening kinky human hair will be greatly appreciated. Please omit name.

M D Chicago

ANSWER—Curling and kinking of the hair are due to peculiar shape and perhaps physical structure of the hair shafts. They can be overcome temporarily by the use of gluey substances such as acacia and quince seed. The anti-kink mixtures are made of some glue or oil in solution in a solution of alcohol and water which is colored and perfumed. When they are put on the hair the liquid evaporates and leaves a coating of the mucilage on the hair which acts so long as it stays on as a sort of straight-jacket to prevent curling.

DIAGNOSIS OF AND DILT FOR RENAL CALCULUS

To the Editor—Will you please give me a list of foods and medication best suited for a patient with renal calculus? Would you advise a cystoscopic examination if there has been one attack in a patient, aged 30, who has been well since, a period of two months? Please omit name
M D, New York

ANSWER—Formerly many types of diets were recommended to patients with renal calculi. These varied with the chemical composition. For those afflicted with uric acid calculi, the diet suggested was purine free with a reduction in the amount of meat and that of glandular organs, if oxalates, numerous vegetables and fruits were proscribed, as spinach, beans, tomatoes, endives, potatoes, plums, strawberries and cocoa or chocolate. Hence by omitting those foods not allowed it was easy to prescribe the proper diet. However, it is questionable whether dietary restriction plays any part in the amelioration of symptoms or the prevention of recurrence. It is generally accepted that the restriction of alcoholic beverages is advisable.

If it is known by roentgenographic examination that the calculus is in the kidney, nothing will be accomplished by cystoscopy. If it is in the ureter and is causing no discomfort it is best left alone, because more than 90 per cent are ultimately passed spontaneously. If there are evidences of irritation as determined by the symptoms or finding of blood cells in the urine, an intravenous pyelographic examination should be made first. If this does not give satisfactory evidence of ureteral obstruction or narrowing, cystoscopy and ureteral catheterization should be done.

ELECTRICAL REACTION IN X-RAY WORK

To the Editor—For the past two years I have been doing my own x-ray work, consisting of about a dozen fluoroscopic examinations and plates weekly. From the beginning of my work, in spite of the use of standard precautions, of gloves, apron and screen, I have felt a tingling and burning of the skin of the arms and legs, quite mild, but lasting many hours and beginning fifteen or twenty minutes after the use of the machine. When I had occasion to make three or four fluoroscopic examinations in one day I noted an erythema of my face with itching and burning that same night. Is it possible that x-rays can produce so immediate a reaction? If unusual sensitivity does permit such rapid response to x-ray irritation do you think it advisable to discontinue this work absolutely? Please omit name
M D, New York

ANSWER—The reaction may be what is known as an electrical reaction and may be electrostatic in nature. These reactions are seen frequently in roentgen therapy and may consist of all the symptoms mentioned, including swelling of some of the deeper organs, such as the parotid glands, and also erythema.

The reactions usually occur within an hour or two, and sometimes within a half hour or less, after the treatment is given, and can usually be prevented by grounding the material used for protection.

True x-ray reactions never occur in less than five to seven days unless they are exceedingly severe, and even then they do not appear for a day or two. The so-called electrical erythema, or electrical reaction, usually disappears within a day or two, while a true x-ray reaction persists for weeks.

One may be able to prevent this reaction by remaining farther away from all metal substances, or by having all metal substances or conductors suitably grounded. It may even be necessary to ground one's apron and gloves. If so, this must be done in such a manner as to provide against electrical shock.

Idiosyncrasy or sensitiveness to x-rays can be easily determined by testing an area of skin one inch square to different amounts of x-rays, one sixteenth, one eighth, one fourth, and so on, of the erythema dose.

DANGERS OF SPRING PESSARY

To the Editor—A married woman, about 20 years of age, has just come to me because of profuse and prolonged menstruation. I removed a 14 karat gold pessary from the uterus, the kind with a spring and prongs. She tells me she has worn this for a year continuously, without even cleaning it. She says she had it inserted because of severe dysmenorrhea. Are these things indicated for dysmenorrhea? If so, when? Are they not dangerous to wear because of possible pelvic or uterine infection? If they are safe to be worn, how often should they be cleaned? Can a woman wear these indefinitely and later hope to become pregnant and deliver?
R ALLEN ERESTONE, M D, Gibsonburg, Ohio

ANSWER—The gold cervical pessary described in this query is one of the most pernicious types of pessary ever devised. Those who use this kind of pessary employ it either to overcome dysmenorrhea or, more often, to prevent conception. It usually fails in both types of indications. Not only does menstrual pain usually persist while the pessary is in place, but in many instances the pain is actually increased. Also many

women have become pregnant in spite of these pessaries, and in one instance, at least, one of the pessaries was found lodged in an otherwise normal placenta. In most cases in which they are effective in preventing conception they accomplish their purpose only because they have produced an infection such as endocervicitis. Much invalidism has resulted from their use, some of the conditions being cervicitis, menorrhagia, parametritis, pelvic cellulitis, pelvic peritonitis, cervicovesical fistula, and even death. Harold O Jones (*THE JOURNAL*, May 14, 1932, p 1738) reports a case in which death resulted from an infection produced by one of these pessaries. This author says "Within the last few years more than a dozen patients have been seen in the gynecologic service at St Luke's Hospital with severe pelvic peritonitis and cellulitis due to infections originating about these pessaries." Most experienced gynecologists can make similar statements.

These pessaries should never be used for any indication. A physician who employs them may be held responsible for any harm that may result from their use.

HOLDING IRRIGATING FLUID IN ANTERIOR URETHRA

To the Editor—In the reply to an inquiry as to the treatment of gonorrhea (*THE JOURNAL*, November 5, p 1623) it is advised that the solution be held for from five to ten minutes, also that, if the infection is confined to the anterior urethra, this region only should be treated. Now, if a solution is retained for ten or even five minutes will it not run back to the bladder, carrying with it the infection? My experience is that it will do so. Please omit name
M D, California

ANSWER—If the anterior urethra is only partially filled with injected fluid, the tonic contraction of the cut off muscle will prevent any of it passing into the posterior urethra, no matter how long it is retained.

If the anterior urethra is distended forcibly, some of the fluid may pass into the posterior urethra as the result of the force used in injecting it or of the increase of intra-urethral pressure from later digital compression of the urethra.

ULTRAVIOLET RAY NOT CONTRAINDICATED IN DIABETES

To the Editor—I have been informed by one technician and by one layman, who gives courses in physical therapy for manufacturing concerns, that ultraviolet radiation is definitely contraindicated in diabetes mellitus. They did not know why this was so. Will you kindly give me what information you have on this?

CHARLES E GILLESPIE, M D, Seymour, Ind

ANSWER—There has been much contradiction as to the use of ultraviolet radiation in diabetes mellitus. The factors of dosage, erythema production and constitutional reaction have not been controlled. Theory has played a large part. Clinical observations have confirmed the belief that ultraviolet radiation when employed in suberythematous dosage or in carefully regulated mild erythematous dosage is not contraindicated in diabetes mellitus.

POSSIBLE TAPEWORM INFESTATION FROM SALTED DRIED BEEF

To the Editor—Is there any possibility of contracting an infestation of tapeworm by eating uncooked salted dried beef, granting that the meat is infected in the fresh condition?

H L BURKE, M D, Nigeria, West Africa

ANSWER—The cysticerci of beef tapeworm (*Taenia saginata*) retain their vitality for a variable period, depending on temperature and other factors. Four days of freezing at from -8 to -10 C kills the cysts and is thought by German sanitarians to be the most practical method of control. Meat properly pickled for a period of fourteen days is likewise considered safe, if brine is injected, a shorter time (seven days) is considered sufficient.

INSULIN IN MALNUTRITION

To the Editor—In regard to the use of massive doses of insulin in the treatment of tuberculosis and malnutrition, is there any possibility of any future detrimental effects?
CARL REICH, M D, New York

ANSWER—Massive doses of insulin in the treatment of tuberculosis and malnutrition have not been used for a sufficient length of time to warrant any conclusions regarding the possibility of a future detrimental effect. The only basis of comparison would be in diabetic patients in whom comparatively large doses of insulin have been used for years as yet, no one has shown any harm from this.

Council on Medical Education
and Hospitals

COMING EXAMINATIONS

AMERICAN BOARD FOR OPHTHALMIC EXAMINATIONS Milwaukee, June 12 Sec. Dr William H Wilder, 122 S Michigan Blvd. Chicago

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY The written examination will be given in cities of the United States and Canada where there is a Diplomate who may be empowered to conduct the examination April 1 The general oral clinical and pathological examination will be held in Milwaukee, June 13 Sec., Dr Paul Titus, 1015 Highland Bldg., Pittsburgh

AMERICAN BOARD OF OTOLARYNGOLOGY Milwaukee June 12 Sec. Dr W P Wherry, 1500 Medical Arts Bldg., Omaha.

ARIZONA Phoenix April 4-5 Sec., Dr B M Berger, 743 E. McDowell Rd., Phoenix.

CALIFORNIA Reciprocity Los Angeles April 19 Sec Dr Charles B Pinkham 420 State Office Bldg Sacramento

COLORADO Denver, April 4 Sec., Dr Wm Whitridge Williams 422 State Office Bldg Denver

CONNECTICUT Endorsement Hartford, March 28 Sec Dr Thomas P Murdock, 147 W Main St Meriden

HAWAII Honolulu April 10 13 Sec Dr James A. Morgan 48 Young Bldg Honolulu

IDaho Boise April 4 Commissioner of Law Enforcement, Hon Emmutt Pfost Boise.

ILLINOIS Chicago April 11 13 Superintendent of Registration, Mr Paul B Johnson Springfield

MINNESOTA Basic Science Minneapolis April 4-5 Sec. Dr J C McKinley 126 Millard Hall University of Minnesota Minneapolis Regular Minneapolis April 18 20 Sec Dr E J Engherg, 350 St. Peter St St Paul

MONTANA Helena April 4 Sec Dr S A Cooney 7 W 6th Ave., Helena

NATIONAL BOARD OF MEDICAL EXAMINERS Parts I and II The examinations will be held at centers where there are five or more candidates May 8 10 June 26 28 and Sept 13 15 Ex. Sec Mr Everett S Elwood 225 S 15th St Philadelphia.

NEW HAMPSHIRE Concord, March 16-17 Sec Dr Charles Duncan Concord

NEW MEXICO Santa Fe, April 10 Sec., Dr P G Cornish Jr 221 W Central Ave Albuquerque.

RHODE ISLAND Providence April 6-7 Dir Dr L A Round 319 State Office Bldg Providence.

TENNESSEE Memphis March 23 24 Sec Dr A B DeLoach, Medical Arts Bldg Memphis

WISCONSIN Reciprocity Milwaukee April 11 Sec. Dr Robert E. Flynn 401 Main St. La Crosse.

ADDITIONAL HOSPITALS APPROVED

The Council on Medical Education and Hospitals of the American Medical Association has given its approval to the following hospitals since the publication of the last previous list in THE JOURNAL, Nov 12, 1932

Hospitals Approved for Intern Training

St Francis Hospital, Peoria Ill
Ball Memorial Hospital Muncie Ind.
St Joseph's Hospital Lowell Mass
Huron Road Hospital Cleveland
Deaconess Hospital Spokane Wash
Sacred Heart Hospital Spokane Wash

Hospitals Approved for Residencies in Specialties

Institute of Human Relations Psychiatric Clinic New Haven Conn
University Hospitals Minneapolis
University of Nebraska Hospital Omaha
Cumberland Hospital Brooklyn
Charles S Wilson Memorial Hospital Johnson City N Y
Middletown State Homeopathic Hospital Middletown N Y
St John's Hospital Cleveland

Michigan Endorsement Report

Dr Nelson McLaughlin secretary Michigan State Board of Registration in Medicine, reports 20 physicians licensed by endorsement from Sept 4 to Dec 26, 1932 The following colleges were represented

College	LICENSED BY ENDORSEMENT	Year of Grad.	Endorsement of
University of Colorado School of Medicine	(1924)	Colorado	
Howard University College of Medicine	(1931)	W Virginia	
College of Physicians and Surgeons of Chicago	(1906)	Illinois Nebraska	
Loyola University School of Medicine	(1932)	Illinois Iowa	
Northwestern University Medical School	(1931)	Illinois	
Lush Medical College	(1910)	(1927)	Illinois

Book Notices

100,000,000 Guinea Pigs Dangers in Everyday Foods, Drugs, and Cosmetics By Arthur Kallet of Consumers Research Inc and F I Schlink of Consumers Research, Inc. Cloth Price, \$2 Pp 312 New York Vanguard Press 1932

This volume has already been highly exploited in advertising and through sensational statements in the press. The book is a compilation of material developed largely through Consumers' Research, Inc. The various chapters concern foods, with especial reference to the dangers from arsenic in the spraying of fruits, cosmetics and tooth pastes, antiseptics, ergot and ether, the advertisements in various periodicals, and a demand for more rigid enforcement of the Food and Drugs Act.

The volume does not seem to have been prepared primarily with the idea of a critical analysis of facts but rather with the idea of telling the story so sensationally that the book would inevitably sell.

There are in the book, exclusive of the index, about 300 pages, and on about 100 of them appears material taken from *THE JOURNAL*, so that if that material were omitted the book would be somewhat of an emaciated corpse. Nevertheless, the authors seem to have swallowed hook line and sinker, the statements made by one Ambruster relative to ergot which have been fully considered in *THE JOURNAL* and which, the authors knew at the time they wrote, demanded more substantiation than Ambruster has been able to provide.

While the authors admit that the advertising carried on in the publications of the American Medical Association is far better than that of any other magazine used as an advertising medium by food and drug manufacturers, they criticize these publications on the ground that the gap between advertising and the exposes made by the Association is not so wide as they could wish. Moreover, their criticisms of the Food and Drugs Administration are on a par with their criticisms of the American Medical Association.

If the authors had themselves ever been confronted with the necessity of passing on hundreds of pages of advertising copy day after day, with the thought in mind of protecting the reader and of giving him that to which he is entitled in the way of both reading material and advertising, instead of being in the position of the paid employees of a research service, who have never been forced to look beyond a test tube, they could not write as they do. If they had had in the development of their material anything resembling adequate biologic and medical advice rather than purely chemical and engineering knowledge, they would not have made as many misstatements and exaggerations as they make. Every physician and biologist knows that there is a difference between *in vitro* and *in vivo* action.

The misconceptions of the authors relative to antiseptics are obvious to any medically experienced reader. Every one knows that antiseptic preparations are to some extent overrated by manufacturing firms. For this reason the Council on Pharmacy and Chemistry has accepted but few of the many antiseptic preparations now offered to the public. However, Kallet and Schlink attack even these few. The basis of their attack is misconception on their part that tests with cultures in liquid or solid mediums tell the degree to which an antiseptic will be effective when applied to an infected wound. This is unfortunately the chemist's attitude in a field in which chemistry does not tell the whole story. Actually, present methods of testing the value of antiseptics as applied to tissue are inadequate.

Their book may serve a useful purpose in awakening some people to a danger that most people now know exists. In the long run it is likely to do more harm by its exaggerations than to accomplish good by the facts which, as has been said, are largely taken from other people's investigations and publications.

The government has in the Food and Drug Administration, the fraud order powers of the Post Office Department and the work of the Federal Trade Commission certain agencies capable of accomplishing good for the public. Like other governmental functions, they are hampered by political influence, by hopelessly inadequate budgetary allowances and by a vast mass of legal restrictions on statute books and even in the constitution of the United States. One is inclined to quote to Messrs Kallet and Schlink that famous phrase which appeared in a western dance hall, "Don't shoot the piano player. He's doing the best he can."

Perhaps it would be well for this review to adopt somewhat the same point of view in relationship to the criticisms of the book of Kallet and Schlink. No doubt, their point that quacks can practice with prospect of little punishment beyond a small fine and the surrender of the material seized is a well established one. Perhaps they find it necessary to overemphasize in a period when every one is shouting in order to get any attention at all. But the fact remains that they have damaged the good as much as they have damaged the evil, and this is the most difficult distinction that any destructive critic or iconoclast has to make.

It would be largely a work of supererogation to attempt to point out each of the individual exaggerations, misstatements and misunderstandings that appear in this book. It is to be hoped that in any future efforts of this character the authors will seek suitable medical and biologic counsel in the fields in which apparently their knowledge is relatively slight.

Nouveau traité de psychologie Par Georges Dumas professeur à la Sorbonne Tome II. Les fondements de la vie mentale. Avec la collaboration de B. Bourdon professeur honoraire à la Faculté des lettres de Rennes, J. Larguier des Bancels, professeur à la Faculté des lettres de Lausanne, A. Mayer professeur au Collège de France, I. Meyerson directeur adjoint à l'École des Hautes Études et H. Piéron professeur au Collège de France. Cloth Price 100 francs Pp 612 with 122 illustrations Paris Librairie Félix Alcan 1932

The second volume of this well known French handbook is concerned largely with physiologic problems on the borderline of psychology. It begins with a general discussion of excitation and movement. These fundamental properties of cytoplasm are traced through their increasing complexities, culminating in the conditioned reflexes of the Pavlov school, which are discussed at length. The chapter ends with a section on muscular fatigue. The second chapter deals with the effect of psychic excitation on the secretory organs, in which the work of Pavlov is again dealt with, as are also the studies on secretion of epinephrine by Cannon and his pupils. There follows a detailed study of the physiology of sensation and then a long section on affective states (the disagreeable and the agreeable pain and pleasure, emotional shock, desires). In the discussion of emotional shock, the work of Cannon and his associates is extensively quoted. In the chapter on instinctive tendencies, little use is made of the results of animal experimentation. The volume closes with a description of images. The author concludes that "images are a kind of thought, they are a figuration of thought, they are signs, they are another formulation at the side of the verbal formulation." While the discussions are scholarly and well documented, the printing is marred by the presence of numerous typographic errors.

Behaviour Aspects of Child Conduct By Esther Loring Richards B.A. M.D. D.Sc. Associate Professor of Psychiatry Johns Hopkins School of Medicine With a foreword by Adolf Meyer Cloth Price \$2.50 Pp 299 New York Macmillan Company 1932

More and more, mental health of children is becoming the active concern of parents, teachers and physicians. Many parents believe that merely having a child gives them complete understanding, but nothing could be further from the truth. Many parents consider themselves able to give expert opinions concerning behavior, while in reality they have little, if any, understanding of the matter. Even those who have made a careful study of psychology of childhood cannot be certain as to the best course to pursue in the solution of childhood

behavior problems. There are many books on child behavior. In this book is a discussion of the problem illustrated by many case reports. There is a discussion of the role of behavior in the field of individual health, followed by chapters on the methods of inquiry into the failure of adjustment, on the relation of physical handicaps to child behavior, and on the importance of habit training in early childhood. There are two chapters on the effects of constitutional handicaps, a chapter on the fears of children, one on the management of adolescence, and one on the delinquent child. The material in the book appears to be sound, but the style of presentation is not such as to make the book easily read. To the average parent the book will not be found of any great value, but for the physician and teacher it should prove helpful.

L'état réactionnel. Évolution du tissu lymphoïde en réaction. Par A. Guleysse Pellissier, professeur agrégé à la Faculté de médecine. Paper. Price 20 francs. Pp 224 with 54 illustrations. Paris: Librairie Felix Alcan 1932.

The author has studied and described the comparative histology, evolution and function of the lymphoid tissue. He defines the state of reaction (*l'état réactionnel*) as the accumulation of lymphocytes in tissues that show no other abnormality, he considers it a stage intermediate between the normal and the pathologic. He found such accumulations of lymphocytes in animals living in insanitary surroundings. He was also able to induce such lymphocytic reactions experimentally in rats by keeping them under unhygienic conditions or by exposing them to the irritating fumes of formaldehyde or of turpentine. Histologically the reactional state is characterized by a hyperplasia of the lymphoid tissues with no other signs of inflammation. The author reviews the anatomy of the lymphoid tissue in the pharynx, thymus, intestine, appendix, lymph nodes and spleen. This part of the monograph is needlessly prolonged and emphasized, since the facts are presented in elementary works on histology. After a discussion of the evolution of the lymphoid tissue in fish, amphibians and mammals, he calls attention to the variability of these structures in individuals of the same species and notes the marked sensitivity to diverse irritations. He finds that the development of the lymphoid tissue parallels that of the individual. It appears after birth, reaches its maximum development in youth, remains stationary in the adult and tends to disappear in old age. In discussing the functions of the lymphoid tissues, the author doubts the purely defensive action of these tissues and suggests that lymphoid hyperplasia may be an injurious reaction at times. He states that the scattered lymphoid tissue may act frequently as a tissue parasite and is particularly susceptible to infection. This monograph is an interesting study on the evolution and function of the lymphoid tissue. There are numerous illustrations and an extensive bibliography, which add to the clarity and usefulness of the contribution.

The Mechanism of Creative Evolution. By C. C. Hurst, Doctor of Philosophy of the University of Cambridge. Cloth. Price \$6. Pp 365 with 200 illustrations. New York: Macmillan Company. Cambridge: Eng. University Press 1932.

The author, a prominent English geneticist who has contributed largely to the knowledge of heredity in poultry, rabbits, roses and man, has given an exceptionally clear account of the detailed mechanisms of heredity and variation. No other book gives so much of the actual evidences on which the chromosomal and gene theories of evolution rest. The book is well illustrated, many of the pictures occupying a full page in fact nearly half of the book consists of illustrations.

While the book presents orthodox modern genetics in language as plain and simple as may be, the author disclaims a materialistic view. Evolution, he says, is not a deterministic machine and creative evolution as we shall see is far from being mechanistic—on the contrary it is peculiarly indeterminate throughout all its phases. The book develops along familiar lines throughout most of its length beginning with an exceptionally clear and intelligible account of mendelian heredity and proceeding to a thorough exposition of the chromosomal mechanisms of heredity, an equally luminous account of chromosomal changes and the bearing of these on the origin of new species and an adequate treatment of gene mutations and their probable role in evolution. So far the plan is familiar. From here on the author branches out into more

speculative fields. In a chapter on the smallest living organisms he proceeds to discuss the nature of "filter-passers" and bacteriophages. From the largest living bacteria measuring 750 micromillimeters in diameter down to the smallest half-alive bacteriophages of 10 micromillimeters or less there is, the author says, a continuous series of sizes. He is inclined to believe that the bacteriophage units are equivalent to single specific genes, that the viruses are groups of specific genes more or less in a free state, and that the simplest living bacteria are more complex groups of genes of two or more kinds enclosed in a cell membrane. According to this view the origin and early evolution of life consists of the spontaneous appearance of numerous free specific genes, which gradually form aggregates and subsequently organize the nuclear and cytoplasmic parts of cells. All further evolution is the direct consequence of more and more complex and specialized gene arrangements. Gene changes are random, chromosomal transmutations are random, the mechanism of mendelian heredity is random, and natural selection is locally random according to the particular conditions of environment. The fact that the mechanism of evolution is the result of the interaction of four random variables points to the conclusion that the whole process is indeterminate and unpredictable. While the author believes that evolution will go on in the future to produce types far in advance of present man, he considers that the particular lines of progress are absolutely unpredictable, except that the next advance must be based on man. He concludes that there are no limits to the advances toward higher powers that may take place in the next thousand million years.

This is a book that is sure to be widely read.

The Haemolytic Streptococci. Their Grouping by Agglutination. By Frederlek W. Andrewes and Ethel M. Christie. Medical Research Council Special Report Series No 169. Paper. Price 1s 3d. Pp 73 with 24 illustrations. London: His Majesty's Stationery Office 1932.

There has long been need for a thorough investigation of the agglutination of hemolytic streptococci to bring some order into one of the most confused fields of bacteriologic research. Considerable progress has been made in knowledge of streptococci and in technic for agglutination since the first articles on agglutination of streptococci were published, also there has been no unanimity of opinion among the more recent investigators as to the possibility of identifying the various pathogenic streptococci by means of group agglutination. This publication deserves the serious attention of all interested in the field, first, because in their investigations the authors have developed and utilized a highly specialized technic necessary to elimination of avoidable errors, and, secondly, because their work is not limited to the streptococci found in one disease but covers the field of hemolytic streptococcus infection in man, including scarlet fever, erysipelas, puerperal sepsis and surgical infections. In regard to scarlet fever, they conclude that there is no one serologic type which can be credited with the causation of this disease but that the property which determines the power to cause scarlet fever is rather the intensity of toxin production than any power discoverable by agglutination. Nor were these authors, despite the refinements of their methods and the painstaking quality of their work, able to identify by means of agglutination specific types of streptococci concerned in the other diseases mentioned.

Psychopathology of Forced Movements and the Oculogyric Crises of Lethargic Encephalitis. By Smith Ely Eliot, M.D., Ph.D. Nervous and Mental Disease Monograph Series No 55. Boards. Price \$4. Pp 219 with illustrations. New York: Nervous & Mental Disease Publishing Company 1932.

The author has reviewed the literature in as great detail as possible abstracting numerous case reports from the published work of previous authors. The method that he uses fails in that he has not digested the various reports, so that the reader does not receive a proper evaluation of the significance of any one. He attempts to use psychoanalytic methods in the study of forced movements, using the same methods that have been applied to respiratory difficulties in epidemic encephalitis. Just what can be obtained from psychoanalytic studies of organic diseases of the nervous system depends to a large extent on the individual point of view. Certainly Eliot's ideas are of great interest but his interpretation is still largely theoretical and requires more proof than he has advanced.

Medicolegal

Admissibility of Hospital Records

(Dunn v. Buschmann (Wash.), 13 P (2d) 69)

The plaintiff's wife was delivered of child by the defendant-physician in a hospital, November 18. Soon after being taken home on December 2 she had a uterine hemorrhage, which continued with increasing profusion until her death. The defendant did not visit his patient from the day she left the hospital (December 2) until December 5, when he ordered her returned to the hospital. She died the following day. The plaintiff, as administrator of his deceased wife's estate, brought suit for malpractice against the physician, claiming that the defendant failed to visit her in response to several telephone requests advising him of her condition and that had he visited her then and acted timely she would not have died. The defendant, on the other hand, claimed that he had not been informed of her condition, that during the three day period that she was at home he had no cause to know or suspect her condition and that it was only on visiting her on December 5 that he discovered her condition. Over the plaintiff's objection, certain portions of the hospital record of the case containing entries made and signed by the defendant, December 5, were admitted in evidence. There was a judgment in favor of the defendant, and the plaintiff appealed to the Supreme Court of Washington.

This court, said the Supreme Court, held in *Toole v. Franklin Ins. Co.*, 158 Wash. 696, 291 P. 1101, that the records of a hospital relating to injuries or sickness of a patient, made by attending physicians or nurses, was inadmissible as hearsay evidence. The hospital record admitted in this case seems objectionable for similar reasons. The first statement of the matter objected to is "Past three days (plaintiff's wife) has had profuse hemorrhages." This manifestly was unknown to the defendant except as he learned it from hearsay when he called on his patient, because he had not seen her during the prior three-day period. The second statement that "this continued for three days without notification of doctor" is clearly a self-serving statement made by the defendant and was intended to negative the defendant's fault in not taking notice of his patient's critical condition prior to his visit. The third statement is that this want of notice was "due to fact that patient was cared for by many friends who attended her for short periods, and none of them were aware of amount of blood lost." This also was unknown to the defendant except as he learned it from hearsay at the time he called on his patient. It is even worse than mere hearsay. It is a mere conclusion based wholly on hearsay. It is plain that the statements contained in the record admitted are hearsay and self-serving and were erroneously admitted in evidence.

The defendant contended that the admission in evidence of the hospital record was without prejudice to the plaintiff, because the facts stated in the record were testified to by the defendant or by other witnesses. Manifestly, said the Supreme Court, this record was introduced in behalf of the defendant to corroborate and support his own testimony touching his alleged neglect of his patient during the three day period. It is well settled, however, that evidence of what a witness has said out of court cannot be received to fortify his testimony in court. The judgment in favor of the defendant was reversed and a new trial ordered.

Hospitals Liability for Hot Water Bottle Burn—The plaintiff contracted pneumonia and was taken to the defendant hospital. While he was unconscious a hot water bottle, wrapped in a towel, was placed in his bed near his feet. The towel became dislodged and the plaintiff suffered a burn on his left heel. He sued the hospital and its superintendent for damages. There was a judgment for the plaintiff, and the defendants appealed to the Supreme Court of Oklahoma. The plaintiff, said the Supreme Court, does not claim that the defendants should not have used the hot water bottle but contends that in using it the defendants failed to exercise proper care and due caution to see that the bottle did not burn him. The defendants owed the plaintiff the duty of protection against their negligent acts. Although the use of a hot water bottle is proper in the treatment of pneumonia,

if it was placed at the plaintiff's feet it should not have been so hot as to cause a burn. There was evidence indicating that it was negligence under the circumstances for the defendant hospital after placing the hot water bottle in the plaintiff's bed not to watch and guard so as to avoid hurting him. The determination of this fact was a question for the jury and the jury was justified in finding that the hospital had been negligent. The jury, however, was not justified in finding that the superintendent had been negligent. There was no evidence that the superintendent had negligently employed incompetent nurses for the hospital. Accordingly, the judgment in favor of the plaintiff was affirmed as to the hospital but reversed as to the superintendent.—*Duke Sanitarium v. Hearn (Okla.)*, 13 P (2d) 183.

Malpractice Right of Physician to Testify Against Chiropractor Using Diathermy Machine—A chiropractor was sued for damages for alleged negligence in administering a treatment on a diathermy machine. Over the defendant's objection, a nonsectarian physician was permitted by the trial court to give his opinion as to whether or not the treatment had been proper. The malpractice of a chiropractor, the defendant contended, cannot be established by the testimony of a nonsectarian physician. But, said the district court of appeal, second district, division 1, California, the use of diathermy is not peculiar to chiropractic practice but is taught and included in the practice of the various schools of medicine. The principal books and journals which discuss diathermy and the use of diathermy machines are written by medical authorities other than those of the chiropractic school. It is clear that the witness was competent on the subject, notwithstanding the fact that he was not a chiropractor.—*Dalton v. Los Angeles College of Chiropractic et al (Calif.)*, 13 P (2d) 546.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Bacteriophage in Treatment of Osteomyelitis—For the treatment of osteomyelitis, both acute and chronic, Albee uses the following method. After completing the usual sequestrectomy and saucerization, he takes a culture. If he has already found a specific bacteriophage from a culture previously taken from an existing sinus, he pours two thirds of a test tube of this phage into and over the wound, so that the whole surface is bathed. He then packs the wound with a mixture of paraffin and petrolatum, usually 75 per cent paraffin to 25 per cent petrolatum. The paraffin and petrolatum are heated and poured in as a liquid or forced in by pressure through a large syringe. In most cases the syringe is the method of choice in order to insure penetration of the mixture to the innermost recesses of the wound. He inserts one end of a rubber catheter through the paraffin-petrolatum wound tampon to the bottom of the bone cavity. He allows the other end to project through the dressings and cast with a sterile gauze or cotton dressing over the end. If the laboratory examination of the culture reveals that it is possible to develop a bacteriophage specific for the organism presented, he injects 10 cc. of this phage through the rubber catheter once or twice a week. Should the bacteriophage appear spontaneously in the wound, injection of the laboratory bred phage is still of advantage in that it accentuates the action of the native phage and may be a more specific one. In large wounds several catheters may be inserted, some of which are multifenestrated. As the catheter is firmly embedded in the paraffin petrolatum tampon, the injected phage fluid cannot flow backward between the catheter and the tampon. It must therefore make its way inward between the tampon and the wound granulations and thus, by reason of its own bulk spread widely. Since the phage is by nature a multiplying organism it will thus automatically spread over the wound surface. At the end of eight weeks the cast is removed and the wound dressed great care being taken not to traumatize the granulating surfaces. If the wound is not entirely healed when the cast is removed he again bathes it with a test tube of the prepared specific phage fluid and inserts a catheter or catheters to the depths of the wound. He uses a paraffin and petrolatum tampon as before and applies a cast for a period of eight weeks. He also takes a culture at this time to determine whether the bacterial flora of the wound has changed and whether a more specific race of bacteriophage can

be obtained. Periodic injections through the catheter should be given as before. The author has recently completed a statistical study of 100 consecutive cases treated by his method, which showed that the average healing time for a case of osteomyelitis so treated is about six months.

Passage of Liquids from Stomach into Intestine—Stewart and Boldyreff describe experiments in which they demonstrated that gastritis and duodenitis inhibit gastric evacuation markedly. Even tap water is delayed two or three times the normal limits. No other liquid leaves the stomach more rapidly than water. Strong alkalis inhibit the emptying of the stomach as much as do acids. Weak alkalis leave the stomach with the same rapidity as weak acids. Gastric emptying is prolonged by alcohol, mustard pepper and so on, some bitter salts and peptone. Temperatures from 2 to 50 C have little effect on the emptying time of the stomach. Duodenal regurgitation is the most important factor in the neutralization of gastric acidity.

Evacuation of Gallbladder—Marrazzi studied the extent of emptying of the gallbladder by a method of quantitatively estimating the gallbladder bile evacuated in normal, fat-fed cats not operated on. Gallbladder emptying was studied in

unanesthetized trained dogs by a new method of visualization (abdominal endoscopy). The mechanism of emptying was further studied by means of drugs and substances known to affect smooth muscle directly or through its nerve supply, and by mechanical and electrical stimulation. Direct observation of the viscus during a period when it was emptying failed to show any muscular contraction. An emptying of the gallbladder was not produced or influenced by drugs that have a definite effect on smooth muscle activity, nor by mechanical or electrical stimuli. The conclusion seems warranted, therefore, that muscle contraction in any way comparable to that occurring in other hollow organs plays little or no part in this emptying.

Relations of Respiratory Conditions to Knee Jerk—King and his associates state that, in the dog with the spinal cord intact, the initial depression of the knee jerk which results from an increase of the carbon dioxide tension of the blood is not due to a direct depression of the spinal reflex centers but to an inhibitory effect from higher centers, due in part to their direct excitation by the carbon dioxide and in part to reflex excitation. The effect of hyperventilation on the knee jerk is that of a mild augmentation, but in animals with the cord intact, inhibitory influences from higher centers may dominate and lead to an actual diminution. The actual excursion of the leg may also be diminished because of the development of a state of rigidity and increased extensor tone. There is no evidence that the effects of hyperventilation are due to tissue anoxia. In the early stages of anoxia there is evidence of a short period of increased excitability of the lower spinal centers. The effects of a severe and prolonged anoxia are always depressant. The lower spinal centers are qualitatively affected by an increase in the carbon dioxide tension in the blood and by anoxia as is the respiratory center, but quantitatively they are much less responsive. The effects of acidosis, alkalosis and anoxia, within physiologic limits, account to but a small degree for the variability in spinal reflex responses and are overshadowed largely by other inhibitory and augmentatory factors.

Nutritive Value of Mineralized Milk—Kemmerer and his associates found that rats reared from weaning on whole cow's milk mineralized with iron, copper and manganese grew from 60 to 200 Gm in thirty-six days. The average daily gain of 3.9 Gm was similar to the gain made by rats on an ordinary ration. To produce a gain of 1 Gm in weight, 2.25 Gm of milk solids was required. Pigs reared on mineralized milk (plus cod liver oil) made an average daily gain of 1.26 pounds over a period of sixteen weeks. The rate of gain was practically identical with that made by pigs on a standard dry ration. Only 1.97 pounds of milk solids was necessary to produce a 1 pound gain in weight, while 3.53 pounds of the dry ration was needed to produce the same gain. The nutritive value and efficiency of whole cow's milk has thus been demonstrated by direct feeding after the deficiencies in the milk were corrected by the addition of inorganic supplements.

Subcutaneous Absorption—In order to determine the rate of absorption of dihydroxyacetone, dextrose, fructose and galactose, Himwich and his associates performed ninety-two experiments in which 50 per cent solutions of these substances were injected subcutaneously. In addition, a 2.5 per cent solution of dextrose was used in sixteen experiments and a 5 per cent solution in thirty-six. At the end of forty-five minutes, the proportion absorbed for each of the 50 per cent solutions was as follows: dihydroxyacetone, 59.3 per cent, dextrose, 48 per cent, galactose, 39.2 per cent, and fructose, 37 per cent. After one hour, 62 per cent of the 2.5 per cent solution of dextrose and 53.9 per cent of the 5 per cent solution had been absorbed. The results indicate, first, different rates of absorption for these substances, secondly, an apparently constant rate of absorption for each substance from a concentrated solution (50 per cent), and, thirdly, a diminishing rate of absorption from a dilute solution (5 per cent and 2.5 per cent).

Active Substance in Anaphylactic Shock—Dragstedt and Gebauer-Fuelnegg report that in the majority of instances of severe or fatal anaphylactic shock in the dog there appears a substance or substances having the property of stimulating smooth muscle (guinea-pig intestine) in the supradiaphragmatic inferior vena cava blood, and in the thoracic duct lymph. This substance apparently disappears or rapidly diminishes as the blood circulates, since it can but rarely be demonstrated in the femoral vein blood.

Amoebiasis in Panama and California—Anderson points out that a relatively high incidence of amoebiasis (*Endamoeba histolytica*) presumably exists in Guatemala, Costa Rica and the interior of Panama. In the Hospital Santo Tomas in Panama City, however, only 13.9 per cent of a selected group of patients (from the men's medical, women's medical and obstetric wards) were found to harbor *E. histolytica*. In recent California surveys in which comparable laboratory methods were used (wet fixed iron hemotoxylin stained smears examined) there has been reported an incidence of from 9.8 to 16 per cent. In 88 of the 101 Panama cases of amoebiasis found on 1,834 examinations the patients were treated with carbaminophenyl-arsonic acid containing 28.8 per cent of arsenic given orally in an average dosage of 5 Gm for ten days. This amebicide was effective without adjuvant in clearing all but one of the thirty-seven patients that could be followed during the month of therapy. No evidence of arsenic toxicity was noted when total doses of 300 mg per kilogram were given orally.

Influence of Race in Malarial Splenomegaly—Carley's report is based on the study of a group of 1,091 Panamanian children (598 Negroes and 493 mestizos) showing evidence of malaria by parasites in the peripheral blood, by enlarged spleen, or by both. Splenomegaly, as a sign of malaria, is more constant in the mestizo than in the Negro. If, in this series, dependence had been placed on splenic enlargement alone, one third of the cases of malaria in Negroes and one fourth of the cases in mestizos would have been missed. An enlarged spleen is more likely to be accompanied by parasites in the peripheral blood in a Negro child than in a mestizo child.

Hydroquinidine in Malaria—Bevil states that, in sixteen smear positive patients with malaria, hydroquinidine sulphate in doses of 10 grains (0.65 Gm) daily for four days about four hours before chill time caused in every case disappearance of parasites from the blood and cessation of symptoms by the fifth day. There were four cases of estivo-autumnal infection, and twelve of benign tertian. So far as concerns the immediate results of a short course of treatment, the conclusion of Giemsa

and Werner was confirmed that hydroquinidine appears equal to quinine in antimalarial activity. Hydroquinidine in a single 10 grain (0.65 Gm) dose of the sulphate daily was well tolerated, producing cinchonism (vertigo) in only one case. In one case this dose was given daily for forty-eight days, and a 5 grain (0.3 Gm) dose daily for the following twenty-five days without ill effect.

Pheochromocytoma—Eisenberg and Wallerstein tabulate the fifty three cases of pheochromocytoma of the medulla of the suprarenal collected from the literature with their main clinical and pathologic features. They present a new case of malignant pheochromocytoma of the medulla of the suprarenal with the following unusual features: (1) coexistence of another primary malignant neoplasm (of the thyroid), (2) widely spread metastases from the pheochromocytoma, with none from the carcinoma of the thyroid and (3) an unusual blood picture. Only five of the fifty-three cases previously reported were malignant all with widespread metastases. Several cases of benign pheochromocytoma with other tumors have been reported. In only one case was a malignant pheochromocytoma associated with another primary malignant tumor. All known cases of malignant suprarenal pheochromocytoma were bilateral. The incidence of the tumor is about even as to sex; it is greatest on the right side and in patients in the fifth decade of life. The most striking histologic features are the greatest imaginable irregularity in the size and shape of the cells and of the nuclei, the chromaffin reaction and the rich vasculature. About one half of all the patients showed hypertension, some with atherosclerosis and others without it. While in some cases of tumor of the suprarenal cortex hypertension was continuous, in a large majority of the cases of tumor of the suprarenal medulla in which it was present it was of paroxysmal type—but only in the cases in which the tumor was benign as all patients with malignant medullary tumor showed either no hypertension at all or hypertension. The attempts to correlate hyperplasia of chromaffin tissue with hypertension are not successful because of the absence of proof that hypersymprenalism exists in such cases and also because it is not at all established that hypersymprenalism is responsible for hypertension.

Amyl Nitrite Test for Spinal Subarachnoid Block—

According to Elsberg and Hare, the effect of the inhalation of amyl nitrite on the pressure in the spinal subarachnoid space is as follows: The dilatation of the blood vessels produces a rise of intracranial pressure with the result that cerebrospinal fluid is expelled from the cranial chamber. The expulsion of fluid occurs somewhat gradually, reaching its maximum in about one minute. As the effects of the drug wear off, the pressure within the cranial cavity slowly falls, as demonstrated by the gradual fall of the column of fluid in the spinal manometer during a period of from two to three minutes. It is probable that the vessels in the vertebral canal also become dilated during the inhalation of the amyl nitrite. When there is no obstruction in the spinal subarachnoid space, dilatation of the spinal blood vessels and the ensuing decrease in size of the spinal pathway is not sufficient to bring about a change in the manometric pressure curve. On the other hand, if there is a growth that encroaches on the canal, the dilatation of the blood vessels of and around the spinal cord (and perhaps of those of the tumor itself) will alter the relative proportions between the size of the vertebral canal and the amount of space occupied by the spinal cord and tumor. Therefore, during the period of inhalation of amyl nitrite the subarachnoid block will become temporarily exaggerated. The authors have made the amyl nitrite tests in sixty-three patients in whom a manometric block was suspected. In thirteen of the patients, a subarachnoid block was demonstrated. The results were so definite that, although their experience with the test in suspected compression of the spinal cord is still small, the following conclusions appear to be justified: 1 In persons in whom a tumor of the spinal cord or some other disease which would produce a spinal subarachnoid block is suspected, the amyl nitrite manometric test is a delicate method for the determination of the presence or absence of a block and for the recognition of the degree to which the free flow of cerebrospinal fluid in the spinal subarachnoid pathway has been interfered with. 2 The amyl nitrite test appears to be more sensitive than the manometric tests made by compression of the jugular veins. In five cases of complete block as shown by the amyl nitrite test, the jugular compression test showed partial block in one, and in another a questionable partial block. In five cases of partial block, as shown by the amyl nitrite manometric test, the jugular compression test gave a questionable result in one and an entirely negative result in three others. In three cases in which there was a marked block as shown by the amyl nitrite test, the jugular compression test showed a marked block in one and a complete block in the two others. In every patient in whom there was evidence of a spinal subarachnoid block by the jugular compression test a block was also demonstrated by the amyl nitrite test. 3 The amyl nitrite test is easy to make and requires no special experience or manipulations. The authors believe that the test is a reliable one and that its simplicity will recommend it and make it valuable for the diagnosis of compression of the spinal cord by tumors and for the recognition of spinal subarachnoid block from other causes.

Interstitial Hypertrophic Neuritis—In a review of the literature on interstitial hypertrophic neuritis, Wolf and his associates found forty cases. Of these, thirteen were clinically typical and histologically proved; four were histologically characteristic but clinically the data were inadequate or had some unusual aspect, twelve were clinically typical but lacked adequate histologic confirmation and in eleven the pathologic

reports were lacking and the clinical features were atypical or ambiguous. The essential clinical criteria of the disease are (1) the signs and symptoms of disease of the peripheral nerves, (2) palpable nerve trunks, and (3) a progressive course. The only exceptions to these criteria were (1) one histologically verified case with a fluctuating course, and (2) one case in which the nerves were microscopically thickened but not to the point of recognition by palpation. One may say, therefore, that occasional cases will be encountered in which the diagnosis can be established only by biopsy. The variable clinical features of the disease are: familial incidence, onset in childhood, motor disturbance with or without sensory loss, Argyll Robertson pupils, intention tremor, ataxia, nystagmus, scanning speech and kyphoscoliosis and other skeletal deformities. Of the twenty-nine cases accepted, thirteen showed a familial history. The onset of the disease was recorded as during the first decade of life in seven cases, during the second decade in six cases, during the third decade in five cases, and after the fourth decade in the remainder of those in which the age was stated. Pathologically, the essential features of the disease are (1) uniform gross thickening of the nerve trunks, of wide distribution, and (2) the characteristic hypertrophy of the Schwann sheaths, which produces the concentric laminated structures that have come to be called onion bulbs. Secondary histologic features are (1) degeneration and shrinkage of the myelin away from the axis cylinder and toward the outer sheath, (2) degeneration and proliferation of the axis cylinder, (3) secondary degeneration in the dorsal columns, and (4) occasional gross thickening of the spinal roots but more frequently microscopic involvement. The authors present the clinical and pathologic observations in three new cases. The patients were two young men and a woman in whom the disease began at the ages of 12, 13 and 26 years. There was no familial history in any of the three cases. The chief clinical features were the signs of a severe, slowly progressive polyneuritis associated with paralysis, muscular atrophy and palpably thickened peripheral nerves. Both the upper and lower extremities were affected, the lower more than the upper. Lancinating pain or muscular cramps occurred in all three patients. Two showed a neuritic type of sensory disturbance. The pupils reacted sluggishly to light in two of the patients and promptly in the third. Fibrillary contractions were present in two of them and absent in the other. None of the patients had scanning speech, nystagmus or evidence of kyphoscoliosis.

Puerperal Morbidity—Philpott states that in the Royal Victoria Montreal Maternity every woman is classified as morbid if her temperature goes above 100.5 F at any one time during her stay in the hospital, excluding the first twenty-four hours following delivery. No matter what is the cause of the abnormal temperature, every case is included. Over a period of many years the general morbidity has averaged nearly 20 per cent. If this general morbidity had been estimated by means of one of the more lenient standards, the percentage would have dropped well under 10 for the same series of cases. To simplify matters, a monthly chart was devised whereby the highest postpartum temperature in every case is recorded. The first twenty-four hours post partum is excluded, but from that time until the patient is discharged from the hospital every day is included. The temperature is taken every four hours during the day at 6, 10, 2, 6, 10 and a single rise above 100.5 F,

from whatever cause, classifies the patient as morbid. This method affords a most accurate means of comparing morbidity from month to month and from year to year. It is particularly useful in hospital practice, in which evidence of infection should be detected early and precautions taken to avert mild or severe epidemics. At the end of each year a composite chart is made readily by totaling the figures of each monthly chart. The author presents this method as a suggestion to simplify the estimation of morbidity. It is certain that if one wishes to compare standards with different localities and with different clinics some definite standard should be taken. It also affords a method of appraising the value of any technic, especially with respect to the use of antiseptics before, during or after delivery.

Multiple Myeloma—Jones reports a case of multiple myeloma in which repeated examinations of the urine have been negative and Bence-Jones bodies have never been found in the urine. He believes that roentgen therapy has definitely retarded and caused regression of the lesion in the localities in which it has been found possible to use it. Unfortunately, its use has been limited owing to the fact that the patient is quite ill for ten days or two weeks following each irradiation. This illness is accompanied on each occasion by a papular eruption of the skin over the malar regions.

Abdominoperineal Excision of Rectum with Primary Healing—Jones and Murray review the case records of eight consecutive abdominoperineal excisions of the rectum. Only one death occurred, and this was due to cardiac failure. A primary closure of the perineal wound would have been obtained without doubt. The average stay in the hospital of the seven surviving patients was forty-six days, the average stay after resection was thirty-five and a half days. Of the four patients operated on in one stage, three were able to leave the hospital in three weeks with their wounds completely healed. A review of the hospital records for the previous ten years showed that the average stay in the hospital following abdominoperineal excision of the rectum was sixty days and that on discharge none of the perineal wounds were healed. When only the cases in which a perineal excision had been made, were included, the average stay was found to have been seventy-one days.

Urinary Casts in Normal Persons—Jamieson points out that exercise brings about transitory changes in the normal kidney, resulting in the excretion of albumin, casts, erythrocytes and leukocytes. These are in excess of normal. The more strenuous the exertion, the more albumin present, as a rule, and the more casts and blood cells. In the less vigorous forms of sport, such as badminton and tennis, less disturbance of renal function follows and fewer formed elements are observed. Even after short periods of time in the lordotic posture the excretion of blood cells is noted. In all the exercise tests made by the author, leukocytes were found more frequently than erythrocytes and the latter more often than casts. This is in accord with the relative proportions in the Addis cast count in normal persons. Albumin was slightly less frequent. Any condition that tends to concentrate the urine and increase its acidity may be responsible for an increase of formed elements. It can readily be seen how applicants for life insurance, candidates for aviation and others desiring a clean bill of health for various posts, both home and abroad, may be postponed or even rejected without just cause. The medical practitioner should be on his guard lest he attribute to pathologic conditions of the kidney the presence of these formed elements in the urine of normal persons.

Intrinsic Cancer of Larynx—Hodge emphasizes the fact that chronic hoarseness in an adult demands a laryngeal examination by a competent physician. The laryngeal examination should be complete and the anterior laryngeal commissure if necessary examined by direct laryngoscopy. If the diagnosis is early, laryngofissure will permit a cure in almost 80 per cent of cases of laryngeal cancer. Biopsy should be a conclusive step in the diagnosis of cancer of the larynx. Operative procedures should follow it as soon as possible. Microscopic grading of carcinoma of the larynx is of definite value, with the clinical examination, in determining the type of treatment used and the prognosis. The author believes that laryngectomy is the operation of choice in all cases of extensive intrinsic cancer. Radium and roentgen irradiation should be reserved for inoperable cases.

Chylothorax and Chylous Ascites—In reviewing the literature, Fletcher found that complete involvement of the thoracic duct with associated chylothorax and chylous ascites is extremely rare and that chylo-ascites is less rare than chylothorax. From a study of the literature and a personally observed case, which he reports in detail, he concludes that surgery is not practical in most cases. Drainage of fluid, other than by aspiration, would apparently invite infection. Chyle should be removed in as small amounts as possible to insure relief to the patient. Cough is an aggravating symptom if the cavity is "sucked dry," and it is conceivable that the negative intrapleural pressure produced by such a procedure would tend to interfere with healing. A certain amount of chyle may be reabsorbed through the lymph nodes, but it is probably negligible. Constant aspiration of chyle soon produces starvation and inanition before collateral chylous circulation can be formed. The mortality in the cases reported in the literature has been between 10 and 50 per cent, most of the patients dying within three weeks. The prognosis depends on the underlying pathologic condition. As carcinomatous metastases were widespread, it seems highly improbable that any treatment would have been successful in the author's case.

Bronchogenic Carcinoma H. M. Horns Iowa City.—p 542

Carcinoma of Cervix—Thomas found that among 387 patients with cancer of the cervix at the Johns Hopkins Hospital only 5 per cent gave a history negative for childbirth or miscarriage. Consequently, in most instances cancer of the cervix is definitely associated with a history of one or more previous pregnancies. Some form of unusual vaginal discharge is the primary symptom in almost every patient. The most frequently encountered symptom is some irregularity in menstrual blood, manifested by a slight prolongation of the normal period, normal duration but more profuse flow, the flow appearing every two or three weeks, regular flow but intermenstrual spotting showing of blood following exercise, or blood after coitus. Pain is never a constant symptom of early cancer. There is only one certain method of diagnosing cancer of the cervix uteri, namely microscopic examination of tissue obtained from the suspected tumor. Every woman who gives a history of intermenstrual bleeding, bleeding after the menopause or any menstrual type of vaginal discharge, should even in the absence of positive physical signs be suspected of having cancer until the contrary has been proved. Biopsy and microscopic examination is indicated if there is an indurated area on either cervical lip, especially if the overlying surface is granular, vegetative or ulcerated and vascular or if there is a hardened or raised area with vascularity, sponginess or a tendency to ulceration on the surface. If the pars vaginalis is normal in appearance but the intracervical mucosa seems vascular or granular the curet may reveal definite intracervical cancer, most often adenocarcinoma. Carcinoma of the cervix must be differentiated from: (1) eversion of the cervix with erosion or granuloma formation; (2) cervical ulceration occurring in cases of prolapse; (3) cervical polyps when they bleed or undergo secondary changes secondary to interference with circulation; (4) nabothian cyst when they cause enlargement and irritate normal cells of the cervix; (5) submucous tissue protruding from the cervix with ulceration and bleed-

ing, (6) interstitial cervical myoma and sarcoma of the cervix, which is exceedingly rare, (7) gonococcal condylomas, and (8) syphilis, chancroid and tuberculosis.

Carcinoma of Stomach—Jenkinson believes that the onset of cancer of the stomach is most frequent between the ages of 40 and 65, with males predominating. The previous observations are usually negative, the patient often stating that he has never been aware that he had a stomach. In a small percentage of cases superimposed on an old gastric ulcer, there may be a history of long standing. As a rule the onset is insidious, varying with the type and location of the lesion. The earliest symptoms are anorexia, discomfort and a feeling of fullness during or immediately after eating, gas or eructation of food, usually absence of pain, marked loss of strength, slight loss in weight and slight secondary anemia. The early physical observations are negative and the diagnosis rests on the history, laboratory observations and roentgen examination. The author concludes that if the mortality rate from cancer of the stomach is to be lowered the diagnosis must be made early. In the majority of cases in which the disease is apparent and readily diagnosed, only palliative treatment remains and the possibility of a cure has long since passed. There are no symptoms or physical, laboratory or roentgen observations that are pathognomonic of this condition. Each case must be considered as a distinct entity. The history, physical examination and laboratory and roentgen observations must be carefully studied and correlated if one is to combat gastric cancer successfully.

Iodine in Treatment of Hyperthyroidism—Winkenwerder and McEachern present the data on 157 cases of hyperthyroidism treated with iodine. In 144 patients the point of maximum improvement was reached in from eight to thirty-two days. The average for the entire series was 13.5 days. An average decrease of 50 per cent in the metabolic rate was obtained regardless of its initial level prior to iodine therapy. No essential difference between cases of exophthalmic goiter and nodular goiter with hyperthyroidism was noted in their reaction to iodine. Of the fourteen cases of the latter type, thirteen showed remissions similar in rate and degree to those exhibited by the entire series. The reactions to iodine were: (1) slow prolonged improvement; (2) reappearance of signs and symptoms of the disease during prolonged administration; (3) two consecutive remissions occurring in the same patient with only a short interiodine period (two weeks); and (4) exacerbation of the disease coincident with iodine administration. The authors place emphasis on the advisability of administering iodine according to a definite course with operation almost without exception. A preliminary preiodine period of general medical care, they believe will produce a greater ultimate improvement than that obtained by iodine alone. Iodine should be restricted with few exceptions in the preoperative preparation of the patient. The authors conclude that the various forms of iodine in use are compound solution of iodine solution of potassium iodide, ethyl iodide gas and solution of sodium iodide. The administration of compound solution of iodine in doses of from 5 to 10 drops daily (30 to 60 mg. of iodine) or potassium iodine in doses of from 3 to 5 grains daily (0.2 to 0.3 Gm.) is more than adequate and allows a wide margin of safety. Potassium iodide or sodium iodide, in aqueous solution has proved a satisfactory form of administration. The authors have obtained maximal remissions in five patients with hyperthyroidism to whom potassium iodide was administered in doses of 15 grains (1 Gm.) daily.

- *Unusual Cases of Migraine with Especial Reference to Treatment A M Goltman, Memphis Tenn—p 51

Allergic Activity of Proteins—Rappaport describes experiments in which he demonstrated that spores of *Bacillus subtilis* when dried in protein material are destroyed by exposure to dry heat at 140 C for two hours. The antigenicity of egg albumin, determined by the skin reaction in sensitive patients, is not affected by heating the dry material at 140 C for two hours. The antigenicity of pollen, determined by the skin reaction and by its effectiveness in the treatment of hay fever, is not affected by dry heat at 140 C for two hours.

Synthetic Ephedrine—Kern and Schenck consider that synthetic ephedrine is probably as efficacious as natural ephedrine in the palliative treatment of asthma, hay fever and vasomotor rhinitis. With neither the natural nor the synthetic product is there any relation of the efficacy of the drug to the duration of the disease or the age of the patient. The acquisition of tolerance was not noted in the case of the synthetic drug, and it was rare and almost negligible with the natural drug. The effect on blood pressure by the synthetic drug when orally administered in 25 milligram doses is somewhat less than that of the natural product. Synthetic ephedrine produces unfavorable side effects in less than 9 per cent of patients as opposed to over 23 per cent following the use of the natural ephedrine. These effects in the authors' experience were usually milder after synthetic ephedrine and in only three observed cases necessitated discontinuance of the drug. This relative freedom from undesirable side effects constitutes a real advantage of synthetic over natural ephedrine. True hypersensitiveness to both natural and synthetic ephedrine has been observed. Synthesis makes possible a constant and stable supply of the drug.

Poison Ivy—Maisel describes a new method of local immunization to poison ivy which involves the direct application of gradually increasing doses of an extract of poison ivy by means of daily baths. This procedure proved harmless and successfully prevented recurrent attacks of poison ivy in a patient in whom all other recognized methods of therapy had failed. In order to obviate the danger of inducing an attack of dermatitis, the initial dilutions must be very great and the concentration must be increased slowly and continuously. The author suggests that other types of contact dermatitis may be treated by this method.

Heat, Effort and Cold Sensitiveness—Duke mentions three types of cardiac disorder: extrasystoles, tachycardia and angina pectoris, which occurred in persons who gave normal physical examinations. These abnormalities could be brought on consistently by the effect of the sense of heat or by effort in three cases and by the sense of cold in the other. They could be relieved by applying an agent the reverse of the one that caused the abnormal reactions. The conditions were benefited by treatment with the agent responsible for the illness. The author believes the disorders are due to disease in the heat regulating mechanism and in these cases by abnormal responses to the sense of heat or the sense of cold by the heat produced by physical or mental effort.

Unusual Cases of Migraine—Goltman emphasizes the fact that persons with migraine cannot be treated as a group but must be treated as individuals. True allergic migraine is

probably hereditary in 100 per cent of cases. Migraine has been classified from a general medical point of view. Foods are of paramount importance in the majority of cases. In some cases positive skin reactions may be obtained, but elimination of these specific foods affords the patient no relief. Inhalants, such as animal hair and danders, pollen, orris root and insect powder, are the main factors in many cases. Elimination of inhalants alone does not always procure relief. Treatment with specific extracts is necessary in some of these cases. A combination of allergic and endocrine migraine is quite common. Combined therapy is necessary for relief.

Effects of Enzymes on Tubercle Bacillus—Berg reports that tubercle bacilli undergoing autolysis in vitro liberated soluble digestion products. Among these were acids and reducing substances. Tubercle bacilli undergoing pancreatic plus autolytic digestion in vitro liberated greater quantities of acids and reducing substances than by autolysis alone. The swelling of tubercle bacilli in suspensions containing added pancreatic enzymes gave additional proof that digestion took place. Autolytic enzymes alone brought one fourth of the weight of tubercle bacilli into solution in four days, and one third in nine days. These proportions were only slightly increased by added pancreatic enzymes.

Are Antiviruses Specific?—Besredka reviews the literature on the specificity of the antiviruses. From the facts reported he concludes that antiviruses are endowed with a specificity as strict as that of the bacteria from which they come.

Variability of Tubercle Bacilli—Rice and Reed found that the S type of various strains of acid-fast bacteria, *Mycobacterium leprae* and human, bovine and avian tubercle bacilli contain antigenic substances not present in the R type of the same strain, dissociation apparently being accompanied by a considerable loss in antigenic complexity. Immune serums prepared against such S organisms contain certain antibodies reacting with extracts of the homologous S organisms but not with the homologous R type, other antibodies reacting with both S and R of the same species and a third type of antibody detected by antigens prepared from the other species of acid-fast bacteria, that is, a group antibody. Antiserums prepared against R organisms, on the other hand, appear to lack the S-specific antibody that is found in S antiserum but contain a much higher proportion of antibodies reacting with extracts prepared from other acid-fast species.

Calcium and Phosphorus of Saliva—In their study of a group of 102 children, aged from 7 to 16 years, Hubbell and Bunting observed no relation between the calcium and phosphorus content of the saliva and the occurrence of dental caries. When the home diet was supplemented by the daily addition of one quart of milk and two ounces of tomato juice, with or without viosterol, there was a slight tendency toward a decrease in the incidence of dental caries. This improvement in tooth condition was not accompanied by any consistent change in the salivary calcium and phosphorus. They present evidence that the volume of saliva secreted in a unit time should be considered in interpreting salivary analyses.

Immunization to Scarlet Fever—Martner states that since the report of the Dicks in 1924 of the isolation of a toxin associated with the streptococcus of scarlet fever interest in the control of scarlet fever has been renewed. The method that he describes differs in several respects from those previously reported. The work is based on skin absorption rather than subcutaneous or intramuscular injection of the scarlet fever toxin. In the preparation of the material he

mixed Dick toxin of a potency of 25,000 skin test doses per cubic centimeter, as standardized by the Michigan Department of Health, with wool fat, so that one tube of ointment (2 cc.) contained 25,000 skin test doses of toxin. The toxin used in making the ointment was freshly prepared and the finished ointment was used within two months after its preparation. The base was perfumed to overcome the odor. In administering the preparation, the patient's back was washed with soap and water, dried thoroughly and then sponged with a 70 per cent alcohol solution. After the excess alcohol had been wiped off, the back was allowed to dry before the material was applied. The contents of one tube of ointment (25,000 skin test doses of toxin) were applied to the cleansed surface and thoroughly massaged into the tissues by the hands. A rubber glove was worn to facilitate the work and to prevent any loss of material by absorption into the hands. In his studies the author observed that scarlet fever toxin combined with wool fat and applied percutaneously by massaging caused a Dick positive reaction to become Dick negative in a large proportion of cases.

Paranasal Sinusitis—According to Loeber and her associates, a roughly triangular swelling of the portion of loose skin beneath the outer third of the lower lid over the malar prominence is pathognomonic of a pathologic process in one or more of the paranasal sinuses of that side. This has been confirmed by roentgenography. The affected sinuses need not be filled with pus to produce the sign, but it is found as well in those sinuses exhibiting only a diseased lining membrane. Amelioration or disappearance of the sign was coincident and proportional with the local improvement of the sinuses involved. The authors believe that the recognition of this sign permits of an early diagnosis of sinusitis which may offset the sequelae of a chronic focus of infection.

Salmonella Food Poisoning—Savage points out the enormous importance of food manipulation, if one deals only with outbreaks of food poisoning due to living *Salmonella* strains. This is not due to the opportunities of infection from human sources, since infection does not occur in that way. There are, however, at least four significant factors. In the first place, the food often is not used fresh as it comes into the place where it is to be prepared (bakery, butcher shop, private home or wherever it may be) but is kept about, either before it is made up into the finished article or after it is so made. Again and again it is shown that the original food is harmless and that the infection with the bacillus takes place on the premises. In many outbreaks the food sold first causes no illness, although the facts suggest that it is already infected, while the food sold last—that is, allowing a longer period for the multiplication of the *Salmonella* bacilli—is the most poisonous, causes the most severe attacks and includes the fatal cases. In the second place, the manipulation often involves heating and then the food is cooled slowly, so that for hours it is at temperatures suitable for the rapid multiplication of any *Salmonella* strains that have gained access either during preparation or subsequently. A third important point but one which applies only to certain foods, is that in many cases jelly or other material particularly suitable for bacterial multiplication is added or is produced in the food as part of the manufacture. The last point is the frequency with which these preparation processes and the conditions of subsequent storage are carried out under totally unsuitable conditions. Undoubtedly these are often minimized in the published report, since attention is not directed to the premises except as a result of the outbreak and consequently some time after its occurrence. Any wide awake food preparer naturally cleans up everything while a veil of reticence and sometimes an exhibition of active

mendacity settles on the personnel. Another factor influencing infection in food poisoning outbreaks is the problem of temperature. The seasonal prevalence of these outbreaks is notorious and it is even more marked when those due to living *Salmonella* strains are considered. Undoubtedly more rapid multiplication of the bacilli in warm weather is an important factor. The increased presence of these bacilli in reservoirs of infection in summer may also play a part, as also may the possibility of fly infection. None of these explanations seem wholly adequate.

Smallpox Vaccination—Roberts describes the use of the subcutaneous and intradermal methods of vaccination over a period of four years among 266 children in an institution. A simple technic was used, which could readily be adopted in ordinary practice. The best results in the work at this institution were obtained by the intradermal method, using living virus in dilutions of around 1:1,000. The reactions were mild, and vesiculation and scarring were trivial or absent. The appearance of vesicles and scars was even less frequent following subcutaneous vaccination with high dilutions, but persistent indurations were occasionally an undesirable result of this method. Subsequent revaccination, sometimes performed as long as four years after the initial vaccination, revealed no appreciable difference in the degree of immunity conferred, as compared with the cutaneous method, irrespective of the dilution. The advantages of the subcutaneous and intradermal methods outweigh the disadvantages, and their wider use is recommended.

Renal Infarction—From a study of a case, which he reports, the literature, and a series of 143 necropsy cases, Barney concludes that 1. Renal infarction occurs in either sex and at almost any age, usually in the adult between the age of 30 and 50. 2. There may be no clinical symptoms to indicate its presence. Whatever symptoms are noted may be

due quite as much to the condition causing the infarction as to the infarction itself. In the event of a total infarction of one or both kidneys, pain and tenderness of definite severity are to be expected. 3. Acute or chronic endocarditis, generally with extensive arteriosclerosis, is to be looked for in the vast majority of these cases. Occasionally, however, infarcts result from chronic or acute sepsis in the presence of a normal heart. 4. Prognosis depends largely on and is really that of the underlying condition, i. e., endocarditis, arteriosclerosis and sepsis. The patient has a poor chance of recovery. 5. No definite rule can be laid down as to treatment. The infarct which causes no symptoms and which cannot be demonstrated during life will generally take care of itself. The treatment of those conditions that favor the formation of infarcts is much more important. These conditions being generally chronic and incurable, their treatment is difficult and of little value.

Massive Intraperitoneal Hemorrhage—Shapira and Starr give a brief survey of the literature and report two cases of massive intraperitoneal hemorrhage which illustrate the essential features of this usually unrecognized condition. The picture that these patients present varies with the amount of hemorrhage. The differential diagnosis of this condition, when associated with severe bleeding, includes lesions of the female genital tract that can produce serious intraperitoneal hemorrhage: ruptured ectopic pregnancy, ruptured corpus luteum cysts of the ovary, and torsion of adnexal tumors. When hemorrhage is not the predominant feature, the condition may simulate that of acute appendicitis, ovarian cyst with twisted pedicle, or perforation of a viscus. The preoperative diagnosis of this condition is difficult. However, acute abdominal pain and tenderness, with signs of hemorrhage, together with the presence of a fibroid tumor, should suggest the diagnosis of intra-abdominal hemorrhage from ruptured veins on the surface of the tumor. The treatment is laparotomy with hysterectomy if the condition of the patient warrants a major intervention. If the bleeding is alarming, blood transfusion and abdominal section, with ligation of the bleeding vessel, have been recommended by Ransohoff and Dreyfoos. One could then perform hysterectomy some time after the patient has recovered.

Tuberculin Test—King used the quantitative intradermal tuberculin test in a series of 225 adults suffering from a wide variety of disorders. The result of the test was in accord with the clinical diagnosis 205 times, or 90 per cent. His results are in close agreement with those previously reported by Atsatt, and by Blair and Galland, in a series of tests on patients with osteo-articular disease. In view of the need for a simple method of determining tuberculous activity in the adult, the quantitative tuberculin test should receive far more consideration than it has been accorded heretofore. The technic he used is as follows: Saranac human tuberculin was procured for use in all the tests. A dilution, strong enough to give a positive skin reaction in patients with proved active tuberculosis and yet weak enough to give no reaction in those in whom there was no evidence of active or recent tuberculous infection, was determined. Forty young adult persons, twenty with proved active tuberculosis and twenty healthy physicians and medical students, were tested. A series of intradermal injections, each consisting of 0.1 cc. of tuberculin, the dilutions of which ranged from 1:1,000 to 1:40,000, were given at the same time to each subject. It was found that the "critical threshold" for the tuberculin used was at a dilution of 1:20,000. At so high a dilution, none but the actively tuberculous persons gave a positive skin reaction. A majority of these gave positive reactions to dilutions of 1:40,000 as well but, since all did not, 1:20,000 was selected as the safe threshold. The tuberculin was diluted with physiologic solution of sodium chloride to which 0.25 per cent phenol had been added as a preservative. All tests were made on the inner aspect of the forearms. The skin was gently cleansed with alcohol and allowed to dry. A careful intradermal injection of exactly 0.1 cc. of the solutions was made at well separated sites, the stronger solutions being injected proximal to the weaker. Separate sterile tuberculin syringes and needles were used for each solution. In most cases, besides the routine injection of the diagnostic 1:20,000 dilution, injections of dilutions of 1:1,000 and 1:40,000 were made at the same sitting. In this way greater information regarding the tested individual's allergy was obtained than when the 1:20,000 dilution alone was used. Those showing no reaction to 1:1,000

were tested with stronger solutions, sometimes with 1 100 or even 1 10. If there still was no evidence of skin hypersensitivity, such people were considered to be entirely free from tuberculous infection. The tests were read at twenty-four and forty-eight hours, the positive reactions almost invariably being maximal at the latter time. An area of erythema, nearly always indurated, 1 cm or more in diameter, was considered a positive reaction to a 1 20,000 dilution, unless the control injection, consisting of physiologic solution of sodium chloride to which 0.25 per cent phenol had been added, also was positive.

Pulmonary Actinomycosis—In reviewing the literature, Genthner and Pendleton found few cases of actinomycosis in which the disease was limited to the lung bed. In reporting the two cases that occurred in one year at the Long Island College Hospital, the authors are attempting to give to the clinician a syndrome on which a reasonable diagnosis of this condition may be made. Pulmonary actinomycosis may be diagnosed by persistent severe pain in the chest, associated with a cough with expectoration of a mucoid and bloody sputum, loss of weight, night sweating, weakness and emaciation. This severe, persistent, boring type of pain is often the patient's dominating symptom and is emphasized by all writers as being most significant. There is usually a slight secondary anemia, moderate leukocytosis of from 10,000 to 15,000, and an increase in polymorphonuclear leukocytes to about 80 per cent. The temperature is septic with an associated rise in pulse rate. This leukocytosis and an increase in polymorphonuclear leukocytes is among the important means of differentiating this condition from pulmonary tuberculosis, with which it is most apt to be confused.

Diagnosis of Duodenal Ulcer—Peter states that for the last twenty years, since he has employed the method of Berg, he has been able to demonstrate sure and objective signs of duodenal ulcer with greater frequency than in the preceding

years of his radiologic experience. He has examined the gastrointestinal tract in 294 cases and found duodenal ulcers in 107. Of these, seventy-nine were severe and twenty-eight suggestive. Of the seventy-nine cases, sixty-six showed the classic symptoms of acute duodenal ulcer. Thirteen presented chronic deformities due to scars. Among the cases diagnosed by the Berg method, a few at operation proved to be ulcer of the duodenum. The number of such cases is, however, limited, owing to the modern conservative method of treatment, which is gaining ground steadily, thanks to this method, which helps one to diagnose the ulcer earlier. The signs seen in the roentgenograms correspond exactly to Berg's objective signs. An adequate technic helps to detect them without fail. It is understood that the radiologist has to be sufficiently experienced in fluoroscopic work to distinguish between a slow peristaltic wave and a constant retraction, a constant niche and a mass of barium retained between the normal folds of the mucosa, a normal recess and a duodenal pouch caused by dilatation, and a deformity due to internal defects and one due to external compression or simple peristalsis.

Relation of Vitamin A to Cancer—Kuh reports that the study of the effect of varying dosages of vitamin A from various sources on the growth of tumors of mice under controlled conditions showed that the tumor implants of mice were not affected by those amounts of vitamin A contained in the usual diet, supplemented by as much as 500 units of vitamin A. On the other hand, when maximal dosages (1,000 or more vitamin A units) of the provitamin carotene were administered, varying degrees of inhibition of tumor growth were observed. The utilization of the carotene was limited by a number of factors, including apparent failure on the part of the animal to convert the carotene to vitamin A, this incompetence being due to the absence from its liver of the enzyme carotenase. The problem of inhibiting tumor growth by means of vitamin A becomes one of determining whether more efficient methods of administration can be devised. Two possible procedures are worthy of trial: (1) the feeding of carotene plus the injection of a source of the enzyme carotenase, and (2) the feeding of new preparations of vitamin A concentrate. The administration of the maximal dosages of vitamin A appeared to be without a harmful effect on the animals. This suggests that the inhibited growth of the tumor is the result of a specific action of the vitamin A on the cancer cell.

Diagnostic Problem in Poliomyelitis—Trask and Harper present data showing that, in twenty-five cases difficult of classification according to accepted criteria, early examination of the spinal fluid did not aid directly in the establishment or the elimination of the diagnosis of poliomyelitis. By this the authors do not wish to imply that spinal fluid examinations are without value in the diagnosis of the disease but rather to emphasize that in their opinion poliomyelitis occurs without alterations in the spinal fluid. It should be mentioned that, from their material, it would have been possible to add to the group presented several additional cases differing in no essential respect but with the early lumbar puncture yielding spinal fluid with from 8 to 12 cells or with fewer cells and a positive Pandy test. Thus every gradation by routine test was found to exist between normal and pathologic spinal fluid, obtained by early lumbar puncture in poliomyelitis.

Patent Ductus Arteriosus—Muir and Brown present twenty cases in which clinical and roentgenologic examination suggested a diagnosis of a patent ductus arteriosus. They consider a combination of any three of the following signs as adequate for a diagnosis: 1. The presence of a continuous or machinery bruit in the second left space. 2. The presence of a long rough systolic bruit with maximum intensity in the second left interspace, with conservation, accentuation or reduplication of the pulmonary second sound. 3. Gerhard's ribbitt dulness. 4. Roentgenologic evidence of dilatation of the trunk of the pulmonary artery. 5. The comparative absence of symptoms. No direct relationship can be established between the presence of a machinery murmur and thrill, or between any degree of dilatation of the pulmonary artery and a machinery bruit. In cases that exhibit Gerhard's dulness, roentgenologic confirmation is always forthcoming. Roentgen examination has a definite value in the differentiation of this condition from some other forms of heart disease in children. Of the twenty patients in the authors' series, seven are males and thirteen are females. The youngest is 5 and the oldest 21. Fifteen of the patients learned of the existence of a cardiac lesion at the routine school examination, and five had the lesion discovered during the course of some infectious disease.

Osseous Dystrophy Following Icterus Gravis Neonatorum—Braid reports a case of osseous dystrophy following icterus gravis neonatorum in a boy who became jaundiced on the second day after birth and whose condition did not arouse anxiety until the tenth day, when he bled profusely from the mouth and umbilicus. A single dose (5 cc) of whole blood, given intramuscularly, caused prompt arrest of the bleeding, but, for the next three weeks, his condition remained critical. The jaundice was apparently stationary, and the stools were consistently colorless. Repeated chemical tests for bile salts and bile pigment in the stools were negative. The liver and the spleen were not appreciably enlarged. At 4 weeks, his weight fell to 2 pounds less than that at birth. Then a gradual improvement set in, and the stools began to assume a normal color. A month after birth, bile pigment was present in the feces but bile salts were still absent. He was entirely breast fed and was discharged at the age of 7 weeks. About a year later he appeared to be well, apart from a certain degree of secondary anemia. He was bright and active in his movements, his mental development was up to normal standard, and there was no lesion of his central nervous system. The only complaint was that he was unsteady on his feet. Roentgen examination revealed a cystic condition of the shafts of all the long bones. While he was kept at rest, deformity of the limbs remained slight, but since he has been allowed to sit up, he has developed a kyphosis and a certain degree of forward curvature of the sternum. Various treatments have been tried: ultraviolet radiation, viosterol, thymus extract and raw thymus and various liver preparations. Throughout, a suitable diet and additional salts were given. No treatment has had any effect and the chief practical consideration has been the prevention of deformity. The author's experimental work on jaundiced dogs produced similar bone changes. He has made a comparison between the bone and nerve changes in rickets and the bone and nerve changes following icterus gravis neonatorum, and he suggests that the liver not only stores vitamins but controls their distribution and activities in normal conditions. This function may be impaired or destroyed in prolonged jaundice, and, as of nervous tissue may ensue.

Hematopoietic Hormone in Pernicious Anemia—The chief points to which Morris and his associates wish to draw attention in the treatment of pernicious anemia with liver and liver extracts are (1) the small volume of material injected (2) the prolonged and sustained reticulocytosis (duration thirty-four days), (3) the maturation of the red cells which eventually took place, and (4) the fact that a single injection produced such a sustained response. Technical difficulties are being encountered in the concentration of swine juice, but in time it is felt that these can be overcome so that material may be available for extensive clinical trial. Their results with human gastric juice have been confirmed by Conner and by Zervas. The authors believe that the absence of Addison in the gastric juice in pernicious anemia is the cause for the reversion to a megaloblastic marrow in this disease. The lack of a satisfactory test for the presence of Addison in concentrated gastric juice, save its injection into a patient with pernicious anemia, is a handicap, as it has been in the case of liver extract and biologically and chemically to try to overcome this difficulty. The observations they have made up to the present time indicate the probability that Addison is the physiologic hormone which maintains the normal state of the blood in health. They have under investigation the therapeutic effect of intramuscular injections of Addison in secondary anemias.

Treatment of Chorea by Baths—Copeman treated a series of forty-four cases of chorea in children under 15 by means of somewhat prolonged immersion in baths at "neutral" temperatures, and general (light) massage. A small control series was treated on orthodox lines. He found that the same result was ultimately achieved in the two groups. The bath group took longer, but the ultimate incidence of relapses proved lower than in the control group. It is probable that a combination of the two methods with ordinary drug therapy would prove a more successful measure than either separately. This could be easily adopted in the hospital, since no special apparatus—other than an ordinary air ring or a canvas bath top cover to fit the ward bath—is necessary. The patients were placed in the ward baths for a period of from one to one and a half hours in the morning and again in the afternoon. The bath was filled with tap water at skin temperature and kept at this point throughout by partial refilling at intervals. Each child had an air ring placed round his neck, which enabled him to lie back in the bath and relax without fear of his head becoming

ing submerged In bad cases, when the danger would still be present, a canvas cover was fitted over the bath, and the head emerged through a hole After the bath the child was put to bed for an hour, and then light skin massage (sedative) was given to the limbs and back for twenty minutes Children with heart disease were also treated in this way but were conveyed on a trolley and lifted in and out of the bath

Gastro-Ileac Reflex in Chronic Appendicitis—MacLean examined roentgenologically 300 cases of chronic appendicitis and operated in 40 He elicited the gastro-ileac reflex by giving ordinary food, such as soup and fish or tea and biscuits, four hours after the barium meal, and noting the amount of barium in the colon one hour later Five hours after taking the barium it will normally be found that practically all the barium has entered the cecum and colon, a few inches of the ileum showing in some cases only At this stage the head of the meal will have reached the hepatic flexure or will be just beyond the flexure. In about 50 per cent of cases, chronic appendicitis causes delay in the filling of the colon Delay in the filling of the cecum under such conditions can be regarded as a sign of chronic appendicitis

*Malignant Disease of Breast Statistical Survey of One Thousand Case Records L B Wevill—p 714

Malignant Disease of Breast—From a statistical survey of 1 000 case records of malignant disease of the breast, Wevill draws the following conclusions 1 The average age of patients with carcinoma of the breast is 53, but compared with the normal population the highest percentage is drawn from women aged 59 2 This disease occurs with equal frequency in either breast 3 It occurs rather more commonly in unmarried than in married women 4 The first indication of the disease in by far the greater majority of patients is the development of a lump in the breast 5 The average duration of the lump before the patients present themselves for treatment is about fourteen months There is nothing to suggest that patients seek advice any earlier at any particular age period or that they are presenting themselves any earlier for treatment now than previously 6 There is no evidence to show that the duration for which the lump has been present is of a definite prognostic importance 7 Pain as a diagnostic feature in malignant disease is of singularly little use and in most cases occurs after the development of the lump 8 The commonest situation in which carcinoma occurs is the upper lateral quadrant of the breast Next in frequency is the centrally placed growth deep to the nipple 9 In an unduly large number of patients the disease is already well established by the time they present themselves for treatment The growth has become fixed and in many cases the skin is already involved 10 The commonest change in the nipple is retraction It is of frequent occurrence, whereas discharge from the nipple or ulceration is much less common 11 A true diagnosis as to the state of the lymph nodes can be made only by a careful histologic examination and the appearance at operation may be misleading When such a microscopic examination is carried out the majority of cases already show involvement of the lymph nodes 12 Family history does not appear to be of any significance in regard to the subsequent development of carcinoma 13 The average mortality from radical excision of the breast in a large series of unselected cases is approximately 4 per cent 14 The majority of recurrences that take place do so within three years from the date of operation and in a series of unselected cases a ratio of cure of approximately 50 per cent is all that can be hoped for 15 Recurrence takes place most often, to start with at any rate in the neighborhood of the original operation The next commonest site is the median sternum and after that the abdominal bone are less commonly affected, but the vertebral column seems to be the site of election in bone lesions

*Influence of Septic Infection of Sphenoidal Sinus on Cerebral Blood Supply F A Pickworth—p 797
Nasal Accessory Sinuses Some Recollections and Reflections H Tilley—p 808

Septic Infection of Sphenoidal Sinus—On the basis of original observations as well as of a review of the literature, Pickworth believes that the most important cause of dysfunction of the brain is to be found in the disturbance of its blood supply Diffusion of soluble toxins from an infected part to contiguous structures is reasonably certain In a series of postmortem examinations, examples were given illustrating the association of diseased sphenoidal sinuses with pathologic changes of the internal carotid artery The author further believes that not only diffusible toxic substances but also actual organisms from a sphenoidal sinus infection may spread centrifugally and so involve the perivascular tissues of the carotid artery In microscopic sections of the sphenoid bone of a man who died of Huntington's chorea with homicidal mania, gram-positive streptococci were found The author believes that organisms occasionally find their way into the perivascular tissues of the smaller brain arteries, where they disintegrate and cause local pathologic changes, such as atherosclerosis The subacute infection occurs most probably by way of retrograde thrombosis of the veins Finally, the author believes that brain changes may be caused by constriction of cerebral arteries resulting from irritation of the sympathetic nervous system Nasopharyngeal sepsis may involve either the nasal ganglion or the cerebral branches arising from the main sympathetic trunk in the neck

Anemia Following Gastric Operations—In a review of the literature Vaughan found that only 122 cases of anemia following gastric operations have been reported in detail, apart from her three cases of hypochromic microcytic anemia and that the available evidence is insufficient to allow the conclusion to be drawn that such operations are necessarily followed by disordered hematopoiesis It is possible that a hematologic and statistical study of a large series of cases might show that at least slight degrees of anemia are more common than appears from a study of the existing material, since Gordon-Taylor draws attention to the fact that in the majority of cases anemia is present without giving rise to any symptoms Again there are not sufficient data available to suggest in the case of

partial gastrectomy, that one method of operative technic is more likely to be followed by anemia than another. Lublin found anemia more commonly in those cases in which the technic of the second operation of Billroth was employed and the pylorus was closed, and considers some modification of the first Billroth operation safer. Morley also favors a modification of the first method of Billroth. That the anemia in the reported cases is dependent on the disordered gastric function due to operative intervention and is not merely incidental is suggested by the fact that a definite proportion of the cases of hypochromic anemia occurs in men. Idiopathic microcytic anemia in man is so rare as to be described as a hematologic curiosity. There is little evidence of the precise nature of the disturbance of gastro-intestinal function. Achlorhydria does not necessarily result. Lublin, Morel and Gordon-Taylor found normal acidity or hyperacidity in a certain proportion of cases even when severe anemia was present. Lublin reports that more than half of his total ninety-eight patients had stools of altered form and consistency. Both he and Gordon-Taylor comment on the increase in fecal fat. It has not proved possible to correlate the occurrence of anemia with any specific changes in the feces. It is interesting, however, that other conditions characterized by faulty fat digestion or absorption are frequently associated with anemia. Changes in the gastro-intestinal function result from operative intervention on the stomach, but their relation to hematopoiesis cannot yet be determined. The results of treatment with liver or iron, according to the type of anemia present, are satisfactory.

*Adhesion Cutting, with Especial Reference to Uses and Limitations of Diathermy and Use of Separate or Combined Endoscope and Operating Instrument F. G. Chandler—p. 49

Activity in Pulmonary Tuberculosis as Determined by Comparative Study of Roentgenograms, Blood Sedimentation and Leukocytic Reactions J. Duffy—p. 60

Adhesion Cutting—Chandler points out that whereas hemorrhage is not common with the electrocautery used at a dull red heat, it is difficult or impossible to control it by this means if severe. Diathermy is, in his opinion, the best method of preventing hemorrhage, and for stopping it. For Maurer's enucleating method, which is probably the best technic of all, diathermy is essential. With a suitable machine, adhesions can be both coagulated and cut by the diathermy current. The machine must be so designed that an adequate cutting current is produced which will enable the wire electrode to cut cleanly, like a knife, without sticking. The author's combined diathermy instrument combines the telescope and coagulating electrode and cutting wire in one, but the illumination is not too good and the field of vision is limited. With a direct vision telescope and anesthetizing needle combined, it is possible to cut by electrocautery or diathermy, through one cannula—a fine electrocautery and a combined diathermy coagulating electrode and cutting wire having been designed to pass alongside the telescope, with this, illumination and field of vision are excellent. In some cases, notably in string, cord and thin, though wide, adhesions, it is easier to cut with the electrocautery than with the diathermy, and in the author's opinion an electrocautery should always be available to supplement the diathermy cutting wire. For the simple cases, one puncture of the chest is all that is needed and, of course, means less manipulation from the patient's point of view and is the best method for beginners. For difficult cases it is better to use two cannulas of equal caliber. Better illumination and perspective can be obtained, and hemorrhage, and in fact the whole operation can more easily be controlled. Moreover, it admits an interchange of operating instrument and telescope, which will often give access to otherwise inaccessible adhesions and allows the use of that invaluable instrument "Maurer's hook." To have right angled, 30 degree and direct vision telescopes is of the utmost value.

Paroxysmal Tachycardia in Children Case, with Inflammatory Lesions of Specific Tissue and Auricular Myocardium. I. Mahaim—p. 752

Essential Tachycardia—Doumer states that, in certain cases, tachycardia which is attributed to neurotonic influences is in reality of myocardial origin. He reports the case of a man, aged 47, who had developed tachycardia following typhoid which had persisted practically unchanged for fifteen years with a pulse of 100 in decubitus and of 120 upright and at rest. Clinically and roentgenologically there was no evidence whatever of myocardial damage, but the electrocardiogram gave evidence of an incomplete block of the right bundle branch. The author thinks that there can be no doubt that the tachycardia was of myocardial origin, especially since the extraordinary instability which characterizes essential tachycardia was lacking and the hypermotivity and anxiety reactions which accompany that form of tachycardia were also absent. However, the author thinks the mechanism producing the tachycardia in this case was not that by which myocardial lesions usually condition tachycardia, that is, the acceleration of the cardiac rhythm was not compensatory because the myocardial alteration was too limited to affect the energy of the myocardial contraction. He thinks that the tachycardia was due to a reflex stimulation of the rhythmic activity of the sinus by the myocardial alterations, while leaving the sinus susceptible to the ordinary physiologic stimuli which explain the variations of the tachycardia.

Pregnancy of Three Months in Patient with Bilocular Uterus with Complete Absence of Cervix P. Guimaraes—p. 512

Retention of Gas and Urine Following Laparotomy—Koukolew recommends the injection of a solution of sodium chloride for the first three days after laparotomy in cases in which there is retention of gas and urine. This therapy causes a reaction characterized by emission of gas, spontaneous micturition, increased muscular tonus and euphoria, the reaction is stronger in asthenic persons than in pyknic ones. This favorable action is the result of introducing salt, fixing water in the organism and obtaining a reaction of the sympathetic nervous system normally accomplished by the exchange of all sorts of matter and by the functions of the secretory organs. The dosage is individual and must take into consideration the results of the blood analysis and the constitution of the woman. For pyknic patients, 10 cc of a 10 per cent solution of sodium chloride may be recommended and for asthenic types, 10 cc of a 5 per cent solution. The injections must not be repeated within less than from two to four hours. The concentration of the solution may be increased to 20 per cent or the quantity increased to 20 cc, but the total dose of sodium chloride given in twenty-four hours should not exceed 11 Gm per kilogram of weight.

Encephalomeningeal Syndrome of Neuromelitococcosis—Rimbaud and Janbon found that the cardinal symptoms of the five cases reported by Rogers as possible late meningeal complications of melitococcosis are the same as those which they observed in two cases of encephalomeningeal disturbances, one of which appeared four years after an attack of melitococcosis.

cocciosis and the other during the course of an infection with *Brucella melitensis*. Some of the symptoms also appeared in cases of other authors. They conclude that there is an encephalomeningeal syndrome of neuromelitococciosis which ordinarily appears late but may appear early, and which is unlike any other known neurologic syndrome. It is characterized by paroxysmal phenomena in the form of paresthesia of the upper extremities, tongue and face, with or without paralysis, dysarthria and aphasia, migraine and visual disturbances, epileptic attacks, and, rarely, abnormal movements. These symptoms may appear singly or together and are accompanied by headache, nausea, vomiting, frequently by fever and occasionally by delirium. The permanent elements of the syndrome are a peculiar mental state, psychic asthenia, indifference, decrease of memory, euphoria, and labyrinthine disturbances, vertigo, tinnitus and deafness. A characteristic neurologic syndrome is lacking except for the frequent appearance of a unilateral or bilateral Babinski reflex. There are no subjective meningeal signs besides headache, nausea and sometimes diplopia, and no objective clinical meningeal signs. The biologic elements of the syndrome are a strong cyto-albuminose reaction of the spinal fluid, with predominant, often severe, hyperalbuminosis, there is frequent xanthochromia. The serum agglutination reaction was positive in one of the two cases in which it was tried.

*Treatment of Chronic Febrile Pleurisy with Methylene Antigen. C. Mantoux—p 95

Chronic Febrile Pleurisy—Under the name of chronic febrile pleurisy, Mantoux discusses a syndrome observed only in young women. It consists in slight but persistent undulating fever of menstrual periodicity, and the presence of spots of dry pleurisy localized preferably at the supraspinous or subspinous level or in the interlobular fissures and characterized by fine, dry crepitations and sensitivity to pressure. The syndrome is characterized further by depression, lassitude, loss of weight, absence of a cough or expectoration and a normal roentgenographic image. The author has found that while this disease, in all but two of his cases, was refractory to the usual forms of tuberculous therapy and prolonged itself for from four to five years, it responded readily to Nègre and Boquet's methylic tuberculous antigen. Among eight young girls treated, seven were cured and one was improved. Within a few weeks the pleurisy, fever and fatigue disappeared and there was a gain in weight. The antigen was administered in progressively increasing doses starting with 0.2 cc of the diluted antigen and going up to 1 cc, each dose was repeated twice, then, starting with the undiluted antigen, the same progression was observed. The injections were given subcutaneously twice a week, they were suspended during the menstrual period. They produced no reaction whatever.

Myocardial Infarct—Buccianti and Supino review the literature on the subject and discuss the clinical, electrocardiographic and anatomopathologic report of a rare case of myocardial infarct with fibrous perforation of the interventricular septum. The patient, a woman aged 70, presented symptoms of cardiac insufficiency and decompensation pronounced edema in the lower limbs as far up as the thighs, pallor, cyanosis of the lips and chest, difficulty in breathing and considerable asthenia. Examination of the heart revealed a blowing murmur which completely replaced the first and second sounds and preceded its maximum intensity over the mitral area, this murmur was not explicable on the basis of valvular lesions but seemed to be due to a marked dilatation of the ventricular cavity and to tearing of the cardiac muscle as found on post-mortem examination. The development of signs of infarct established by electrocardiographic observations during the first days coincided with the detachment of an embolus from the first branch in the descending anterior branch of the left coronary

artery, and the gradually occurring coronary obstruction of arteriosclerotic nature could not in itself cause necrosis with ensuing perforation of the septum because a collateral circulation through anastomosis with the right coronary artery was established. The modifications of the cardiac rhythm, such as nodal rhythm and atrioventricular dissociation, were not explained by anatomic alterations of the sino node or the node of Aschoff and Tawara. The integrity of these centers proves that the alterations of the cardiac rhythm were of a purely functional character, and this is confirmed by the successive electrocardiogram taken during the course of the disease, in which the dissociation between the auricles and the ventricles was no longer observable. The electrocardiographic characteristics of the T wave (rounded wave, coronary wave, distinctly negative T wave in the three leads) represented the usual sequence of myocardial infarct and confirmed the evolution of the electrocardiographic signs caused by the infarct itself. The author considers the fibrous perforation of the septum an epiphenomenon of the embolic infarct. Its particular anatomic disposition showed that it could not have brought a notable disturbance into the circulatory mechanism, even from the symptomatologic side the blowing murmur did not vary in its characteristics. The clinical signs presented by the patient in the deteriorating course of her disease, intense dyspnea and retching, did not coincide with the perforation, which in all probability preceded it. These signs were due to the absolute insufficiency of the heart, the result of myocardial sclerosis. The author states that the deterioration was the result of cardiac hyposystole, hypothetically associated with the establishment of an aneurysm at the apex, the altered circulatory mechanism, general stasis and pronounced anasarca contributed toward rendering the cardiac insufficiency irreparable and leading to death. The author concludes that this case is important not only because of its clinical and electrocardiographic value but also because it belongs to those rare cases of myocardial infarction with insignificant beginning but with sudden manifestation of irreparable cardiac insufficiency, the recognition of this phenomenon is now made possible by electrocardiographic examination.

*Atypical Gnat Bite Reactions (Culicosis Bullosa). H. G. Bode—p 7

Dermatomyositis. E. Bender—p 13

Melanosarcoma with Unusual Metastasis—The clinical history of a patient with multiple melanosarcoma is reported by van der Kaaden especially on account of the unusual location of one of the metastases. The patient, a man aged 44, had been well until 1930. Then a nodular growth developed on the posterior portion of the thigh and was removed by the patient's physician. A new growth developed a short time after the excision, soon it reached the size of an apple and the inguinal lymph nodes on the left side became swollen. Both the growth and the lymph nodes were surgically removed and the histologic examination of the tumor revealed it to be a melanosarcoma. In spite of the fact that the operation was followed by irradiation with radium and roentgen rays, a new relapse could not be prevented. The most unusual of the metastases was a soft, pedicled nodule, the size of a cherry, in the left side of the mouth at the edge of the lower jaw. The author thinks that this localization of a melanosarcoma has not been reported heretofore. In discussing the treatment of melanosarcoma he warns against the use of the knife. He considers electrotomy, with a wide coagulation zone far into the healthy tissue, the best treatment of primary melanosarcoma.

Atypical Gnat-Bite Reactions—Bode describes a bullous skin disorder that so far has been observed only in women. It appears on the uncovered or on the lightly covered portions of the body on the face, the hands and especially the legs. Isolated round blisters develop on the otherwise unchanged skin. They have a serous content and reach full size (sometimes nearly the size of a walnut) within twenty-four hours. The surrounding skin shows no inflammatory reactions, unless the content of the blisters becomes turbid by secondary infection and a narrow red halo results. The eruption develops only in the summer months, and this, together with the observation that only the uncovered or the lightly covered parts of

the body become affected, makes it appear likely that gnat bites are the cause. This opinion has been expressed by the French author Genner and recently also by Siemens in Holland. In accordance with this etiology, Siemens designated the condition as *culicosis bullosa*. The clinical histories described by the author are those of two sisters who developed the eruption during the last three summers. The anamnesis revealed that they had been exposed to gnat bites. Because the author thought it probable that this reaction was a manifestation of hypersensitivity to gnat bites, he made cutaneous tests with extracts from *Culex pipiens* and obtained positive results in one of his patients.

blood stream temporarily, yet this does not justify the designation of the condition as sepsis. The diagnosis of sepsis is permissible only if the invasion advances unchecked and leads to severe systemic disease with symptoms in distant organs which do not belong to the typical aspects of the primary infectious disease. In some instances it is of course difficult to draw the line. The chronic forms of sepsis are frequently characterized by symptoms such as a large tumor of the spleen and swelling of the liver. In discussing the symptomatology of sepsis, the author describes the aspects of otogenic, stomatogenic, puerperal, enterogenic and urinary forms of sepsis and shows that sepsis may also originate in the bone marrow, in the endocardium and in the lungs. Concluding, he states that a completely developed sepsis is a condition that is produced when, in the combat between an infectious process and the immunization powers of the organism, the infection proves the stronger and a generalized infection of the organism sets in. However, there are also abortive forms of sepsis, in which the line cannot be drawn between typical infectious diseases and sepsis. Two factors are essential for sepsis: the infection and the permanent or temporary insufficiency of the reticulo-endothelial system.

Treatment of Scars and Keloids—According to Stein,

cicatricial changes of the skin are the result of destruction of the papillary layer. Cicatrices may occur in various forms. The least noticeable, or smooth ones, are even with the surface of the skin and become manifest either by hyperpigmentation or by depigmentation. The mildest preparations that have long been in use to counteract superficial hyperpigmentation are aqueous solutions of sodium borate or solutions of corrosive mercuric chloride. Other bleaching agents mentioned by the author are a bismuth ointment, weak acids and hydrogen dioxide preparations. Depigmented, whitish scars can be covered up with a suitable cosmetic or can be colored to harmonize with the other portions of the skin by application of fluids, such as a solution of potassium permanganate. If the skin becomes too dark by the application of this substance, it can be made lighter by the use of an aqueous solution of oxalic acid. The following method frequently proves helpful when the depigmented scars are still new. The area around the scar is covered with adhesive plaster and after an alcoholic solution of oil of bergamot has been rubbed on the whitish scar, quartz lamp radiation is applied. Cicatrices that are not level with the surrounding skin should be softened and smoothed out. Into this group belong particularly the scars resulting from acne vulgaris, acne varioliformis and variola. Softening can be effected by the pepsin poultices recommended by Unna. Kromayer overcomes slight differences in the level by grinding them off. The scars of variola and acne can also be treated with repeated scarifications or by application of carbon dioxide snow. The latter should be employed so that there is no scab formation but only peeling. The author found diathermy effective in cases of this type. Scars that adhere to the underlying tissues can be mobilized by injections into the rigid tissues, or Extensive scars may develop into tumor-like formations. These so-called cicatricial keloids are best influenced by irradiation. The author recommends unfiltered rays for new, still soft keloids and filtered rays for the older, deep seated keloids. The surrounding areas should always be covered.

Etiology and Symptomatology of Sepsis—Falta shows

that from the standpoint of the clinician it is important that sepsis develops in two different forms (1) the nonmetastasizing form, which is septicemia or sepsis in the restricted sense of the word, and (2) the metastasizing form, in the course of which metastatic abscess formation takes place in the various organs, this is pyemia in the older sense of the word. The author further discusses Schottmüller's theory of cryptogenic sepsis, but he thinks that the assumption of a septic focus, from which infectious agents enter the blood stream again and again, does not solve the sepsis problem completely. He points out that in the various infectious diseases bacteria enter the

disturbances, on the other hand, it did give a positive reaction in one patient without hepatic disturbances. The Takata reaction, first devised as a test for the cerebrospinal fluid but later adapted as a functional test of the liver, gave somewhat more exact results than did the galactose test. Of the reactions for the excretory function of the liver, the bromsulphalein test and the bilirubin tolerance test were tried. The latter, without the aid of other functional tests and without clinical signs, never gave indications of a disturbed hepatic function. Initial insulin hyperglycemia, recommended by Bürger as a functional test of the liver, likewise was found to be unreliable. In summing up their experiences with the functional tests, the authors state that they were not an aid to a more reliable and a more rapid diagnosis than are the customary clinical methods. They maintain that clinical observations and anamnesis, palpation, hepatic fetor, examination of blood and urine, including the aldehyde reaction and the determination of amino-aciduria, are still more reliable in determining the function of the liver than are other methods that may have a theoretical interest but are unreliable, time consuming, expensive and unpleasant for the patient.

Staphylococci in Pathogenesis of Secondary Urinary Calculi—According to Hryntschak, concrements of the urinary passages are the result of a disparity between the colloid protection in the urine and the quantity of the crystalloids in the supersaturated solution. The colloids may either be diminished or changed, or there may develop colloidal substances that are foreign to the urine and that have an especial adsorption capacity for crystalloid substances. In the case of the crystalloid substances, the quantity present in the urine and especially the hydrogen ion concentration of the urine are partly determinative. All this shows that the process of the formation of a concrement is a complex one and for this reason a single change in the urine is not sufficient, but it is necessary that several causal factors concur. In the course of studies on the causes of concrement formation the author found it advisable to differentiate between the primary concrements that develop in noninfected urines and the secondary concrements that result from urinary infection. The author's material is comparatively small and does not permit general conclusions but he thinks that a staphylococcal infection of the urine and symptoms that indicate a renal disturbance make a secondary calculus probable. To illustrate the role of staphylococci in the development of calculi, he gives short reports of four cases. He also tried to demonstrate in animal experiments that a staphylococcal urinary infection has an influence on the development of secondary renal calculi. Injection of staphylococci into rabbits, in which a slight stenosis of the left ureter had been produced resulted in the development of renal gravel in a comparatively high percentage of the animals. Microscopy revealed that the gravel consisted of refracting spheruliths and chemical analysis showed that it consisted of calcium phosphate and carbonate. In animals that were treated with other bacteria gravel formation was never observed and in twelve control animals only one case of gravel formation was noted. In his conclusion the author points out that a hematogenic coccic infection of the urine may lead to the formation of the nucleus of a calculus but of course only when a number of other predispositional factors are present among these the type of coccus the condition of the urine and of the urinary organs and the frequency of bacterial invasion are important.

Flocculation Reactions in Diagnosis of Neurosyphilis—On the basis of his observations Scheller maintains that the Kahn reaction and the Muller conglobation reaction are, in regard to their final results equivalent reactions. The clarification reaction is somewhat inferior but still surpasses the Wassermann reaction. It is advisable to perform several flocculation tests simultaneously because this is the only means by which nonspecific results and technical mistakes can be excluded. It thus is not possible the Kahn reaction should be done because it has the advantages of greatest exactness comparatively simple technique and rapidity. The Kahn reaction proved so valuable in tests on 10,000 serums and on 6,000 cerebrospinal fluids that the author would not dispense with it. He admits that the Muller conglobation reaction II is just as exact as the Kahn reaction but its technique is more complicated. The Muller clarification reaction is simple and reliable but compared to the Kahn reaction it has the disadvantage that the reaction cannot be read until the following day. The diagnostic

significance of flocculation reactions becomes evident in disorders of syphilitic origin in which the Wassermann reaction is frequently negative, as in cerebrospinal syphilis and in tabes. Another advantage lies in the fact that, in polyclinics and in hospitals for internal diseases, the diagnostically indispensable spinal puncture will be made sooner if the blood tests indicate a former syphilis. Thus the patient with incipient or symptomless neurosyphilis will receive treatment sooner than was formerly the case. However, the author admits that he does not know to what extent the positive outcome of these sensitive reactions can be made the criterion of therapeutic requirements or of therapeutic efficacy in neurosyphilis.

Hemolytic Icterus—Meinertz shows that the symptomatology of icterus varies widely. Some persons with icterus have no yellow discoloration of the skin and do not feel ill, consequently, some authors prefer the term hemolytic anemia. This is not satisfactory, since anemia may also be absent, moreover, the term is not specific enough, because numerous disorders may cause increased hemolysis. The term familial hemolytic anemia would be better, but the disorder is not always familial, yet the author admits that the familial or the hereditary form presents a well defined symptomatology. On the basis of two case reports he discusses the main symptoms, particularly the increased bilirubin content of the blood, the reduced resistance of the erythrocytes and the role of the spleen. He concludes by calling attention to certain similarities between hemolytic icterus and pernicious anemia.

Basophil Stippling in Contracted Kidney—Litzner observed stippled cells in six out of eight patients with secondary or with genuine (arteriosclerotic) contracted kidney. He states that lead poisoning could be excluded in these cases but that anemia existed and that substances which should be eliminated in the urine were retained in the blood. He thinks that the occurrence of stippled cells is probably partly the result of anemia, since, according to Naegeli and others, stippling may develop in various types of anemia. But in anemia the stippled cells are usually less numerous than they were in these cases of contracted kidney, and the author thinks that the retention of the substances that should be eliminated in the urine particularly the aromatic substances, is probably also a pathogenic factor of stippling. The type of stippling observed by the author in his patients did not differ from that which occurs in lead poisoning. From this he concludes that, if stippled cells can be observed in contracted kidney not caused by lead poisoning stippled erythrocytes can no longer be considered as the pathognomonic symptom of lead poisoning.

Impairment of Cardiac Muscle Following Poisoning with Acetylsalicylic Acid—Mann describes the clinical history of a man, aged 38 who attempted suicide by taking 30 Gm of acetylsalicylic acid. The case is noteworthy because of the development of a circulatory disorder which was not produced as is sometimes the case in poisoning with salicylic acid by failure of the peripheral circulation but by a deficiency of the heart as a result of impairment of the cardiac muscle. The author thinks that the cardiac impairment was produced by two factors salicylic acid and hunger for the patient had been without food for two days at the time he attempted suicide. Hunger reduces the glycogen content of the liver and also produces acidosis. It is assumed that the glycogen deficiency retards the elimination of the salicylic acid and that the action of the poison is prolonged. The clinical significance of this case lies in the fact that it emphasizes the necessity of caution in the use of salicylates and of acetylsalicylic acid. The author points out that recently large doses (up to 15 Gm daily) of sodium salicylate have been recommended for the treatment of acute articular rheumatism. Such large doses can be tolerated only (as is rightly pointed out by the proponents of the treatment) if given together with large amounts of

Diagnosis of Acute Surgical Diseases of Abdomen—Grasmann shows that the majority of erroneous diagnoses in acute surgical diseases of the abdomen can be avoided by giving attention to the following factors 1 An exact anamnesis should be taken, and all statements of the patient should be given consideration 2 Even in "classic" diseases, not only should attention be given to the local symptoms, but the heart, lungs, kidneys and nervous system likewise should be carefully examined 3 Douglas's culdesac must be systematically examined It is necessary to determine the susceptibility to pressure and pain during movement of the cervix uteri, the condition of the pelvic organs and contents of the culdesac 4 Percussion is of great help for demarcation of the disease focus and has great diagnostic value, particularly in sensitive and obese patients and in appendicitis of the aged and abdominal disorders of children

Glycogen Disease—Schall discusses his observations on three children, aged 8 years, 4 years and 1 year, respectively, who showed the syndrome that von Gierke has designated as hepatomegalia glycogenetica The most important symptom is an enormous enlargement of the liver, noticeable during the earliest period of life The underlying cause of the hepatic enlargement is a glycogen stasis The second cardinal symptom is hypoglycemia without the clinical signs of the hypoglycemic syndrome A third factor is the impossibility of glycogen mobilization by epinephrine Other less constant symptoms are obesity, ketonuria and weakness of the skeletal muscles The disease does not take a rapid course, one case, under the author's observation for almost four years, having remained practically unchanged In spite of the large amounts of glycogen that the organism holds in storage, the low blood sugar content is probably due to carbohydrate hunger of the tissues The author points out that tests made by other investigators seem to indicate that a functional disturbance of the liver diastase is the primary cause of glycogen disease The main object of his report is to call the practitioner's attention to this condition and to stimulate further studies

Occupational Skin Diseases of Photographers—Freund points out that the preparation of negatives and matrices necessitates contact of the hands with the various photographic developers Substances, such as metol, hydroquinone, paraphenylenediamine, diaminophenol hydrochloride, chloroquinone and, to a lesser degree, also rodinal (which contains para-aminophenol), ferrous oxalate and the aqueous solution of corrosive mercuric chloride may cause pernio, erythromelalgia or weeping eczemas Prophylactic measures,

such as the wearing of rubber gloves or covering the fingertips with wax or paraffin or rubbing the hands with a 5 per cent solution of formaldehyde, have not proved satisfactory The stand and tank development that is now often used in roentgenology has likewise disadvantages The author states that his experiences do not corroborate the claim that tank development is more rapid and he asserts that the method produces poor negatives He then describes a method that he devised to prevent contact of the hands with photographic developers Two loops of a flexible material are fastened on one side of the film or on two corners, with the aid of these loops the films can be placed into and taken out of the developing fluids without necessitating contact of the fingers with the films and, with the aid of devices that the author constructed for this method, the procedure is simple and the films can readily be handled in absolute darkness

Methods of Examination in Neurology—Hoff discusses the significance of the various reflexes in the diagnosis of disorders of the central nervous system Certain abnormalities in the position of the head become manifest, for instance, in tumors of the cerebellopontile angle, or in cysts of the corpus callosum or the rhomboid fossa or in tumors of the inferior veriform process of the cerebellum However, it should not be overlooked that abnormal positions of the head may also be caused by pathologic processes in the cervical vertebrae After evaluating the significance of certain reflexes of the eyelids in facial paralysis, the author discusses abnormalities in the posture of the body as a whole, also certain static reflexes of the hands and arms, particularly a tendency to pronation or to supination, and shows their importance in the diagnosis of lesions of the cerebellum Magnus's supporting reaction, the grasping reflex to which Schuster called attention, and certain abnormalities in walking have diagnostic significance in tumors of the frontal lobe A turning of the entire body and of the extremities following a turning of the head may indicate a tumor of the parietal lobe The author further calls attention to pharmacologic tests, because failure to respond to certain pharmacologic preparations indicates lesions of the centers in which the pharmacologic preparation has its point of attack Benedek's percussion of the cranium is helpful in the localization of superficial tumors, and Weisenberg's method of irradiating the cerebellum and the frontal lobe of the cerebrum with short wavelengths, although still in the experimental stage, may eventually prove of great diagnostic value

Parathyroid Extract, Osteitis Fibrosa, Kidney Stone—Mandl claims that he was the first to remove a parathyroid tumor successfully in a case of osteitis fibrosa generalisata (1925) The patient's calcium metabolism returned to normal and his general condition became much improved Subsequently Hellstrom collected from the literature thirty-five cases in which operation was successfully performed At present the literature contains about fifty cases The fact that osteitis fibrosa generalisata could be produced experimentally by administration of parathyroid extract suggested that the disease is caused by hyperfunctioning of the parathyroid glands His first patient had several severe attacks of kidney stone colic Examination of the histories of cases of osteitis fibrosa revealed the frequent incidence of kidney colics, of roentgenologic shadows in the kidneys, or of kidney stones at postmortem examination The occurrence was too frequent to be regarded as a coincidence It suggested that deposition of calcium was a common symptom in osteitis fibrosa Mandl and Uebelhör performed the following experiment Male guinea-pigs were first examined roentgenologically to determine the condition of the bones and the possibility of stones in the kidneys Ten units of parathyroid extract was injected daily for four weeks

In addition, urinary stasis was established by clamping the penis with a rubber clamp for from ten to twelve hours daily. At the end of four weeks the animals were killed and the bodies studied roentgenologically and then dissected. The long tubular bones showed typical early changes of osteitis fibrosa. In three animals the renal pelvis contained a white hard body which on microscopic examination proved to have a crystalline formation. Histologic preparations of renal tissues demonstrated the presence of calcium casts. The conditions described were absent in normal animals. The authors believe that they have thrown some light on the problem of stone formation in human beings.

Chordotomy in Uterine Carcinoma.—Henkel points out that in uterine carcinomas the same treatment may produce entirely different results in apparently identical cases. A therapy that effects a cure in one case may not only be without effect but even be the cause of a more rapid spreading in a similar case. A definite prognosis is thus almost impossible, and the author thinks that in every clinic the number of cures of uterine carcinomas is surpassed by those that are inoperable or that have been unsuccessfully irradiated. This state of affairs makes it necessary to improve the palliatives, particularly the measures for counteracting pain. Since morphine is not tolerated by some patients and its analgesic action is only of short duration in others, the author resorted to chordotomy. Simple division of the posterior roots is not sufficient, but the anterolateral columns of the spinal cord must also be divided. The author reports the clinical histories of three cases in which he resorted to this operation. He thinks that chordotomy should be done as soon as it has been determined that the pains are really the result of the carcinoma and are not produced by inflammatory infiltrations in the pelvic tissues. He realizes that in one of the reported cases chordotomy could have been done six months earlier and that the woman could have been saved from much suffering.

Resection of Nervus Praesacralis.—After mentioning different authors who have tried to influence certain pelvic neuralgias and organic disturbances of the uterus and of the adnexa by excluding the sacral portion of the sympathetic, Cotte relates his own experiences with the exclusion of the superior hypogastric plexus. At first he followed for several years Lichner's suggestion and treated such conditions as dysmenorrhea, amenorrhea and neuralgias of the pelvis by bilateral periaxillary sympathectomy, then he conceived the idea of resecting the nervus praesacralis (superior hypogastric plexus). He has performed approximately 200 such resections in the last eight years and has found that it was a valuable palliative measure in inoperable and relapsing carcinomas of the cervix uteri but he considers its curative value of more importance in certain painful conditions especially dysmenorrhea. He has resected the superior hypogastric plexus in 125 patients with dysmenorrhea. Dysmenorrhea was the main reason for resorting to the exclusion of the hypogastric plexus in nine-tenths of the women. In some cases still other disorders existed which could be traced to a disturbance in the hypogastric plexus such as vesical catarrh, leukorrhea and

dyspareunia. Other painful conditions that justify the operation on the sympathetic are vaginismus and certain neuralgias of the pelvis. In regard to the latter it is stated that, before resorting to resection, the surgeon must be positive that the neuralgias are really only pelvic neuralgias and are not caused by anatomic or functional disturbances in the utero-ovarian plexus. But the author has performed the operation on the sympathetic also in vasomotor, sensory and secretory disturbances. He has seen cases of essential leukorrhea and of nervous hydorrhea, and a case of abnormal dryness of the vaginal mucous membrane after hysterectomy, that were cured by resection of the superior hypogastric plexus. He further reports that the resection was effective in cases of dyspareunia, vaginismus, frigidity, nymphomania and pruritus of the vulva or the perineum. Reflex disturbances that originate in the uterus, particularly those of the beginning stage of gestation, and certain trophic disturbances of the genital apparatus could likewise be influenced by means of the resection.

Resection of Nervus Praesacralis. Operative Technic

—In describing the technic of the resection of the superior hypogastric plexus, Cotte discusses the anesthesia, the abdominal incision, the intraperitoneal procedure, the sutures and the postoperative treatment. He generally employs spinal anesthesia because it effects complete relaxation and facilitates the approach to the promontory. He usually makes the abdominal incisions according to Pfannenstiel's method, in order to have the resulting scar in the region of the pubic hair. He uses the median section only in cases in which the pelvic neuralgias result from inoperable carcinoma. In describing the intraperitoneal procedure, he states that, after opening the peritoneum, he generally extirpates the appendix before bringing the patient into the Trendelenburg position. Then, after examining the genitalia, he searches for the nerve, which can be found on the fifth lumbar vertebra, a little above the promontory. After giving several other pointers as to how the nerve is to be localized, particularly in relation to the common iliac artery and to the superior mesenteric vein, the author states that he makes an incision (usually from 4 to 5 cm in length) into the posterior portion of the parietal peritoneum. The superior hypogastric plexus can be found within the connective tissue seen through this incision. It is essential that the entire nerve is reached and not only some of its fibers, and for this reason the bifurcation should be watched for. The author resects from 2 to 4 cm of the nerve, but he admits that a more extensive resection is permissible. Then the posterior portion of the parietal peritoneum is sutured, and in most cases fixation of the ligaments according to Doleris-Gilliam-Pellanda is done. The suture of the abdomen and the postoperative treatment are the same as in other gynecologic operations.

Erythrodermia and Uterine Carcinoma.—Schweigl gives the clinical history of a woman in whom erythrodermia occurred with carcinoma of the vaginal portion of the cervix uteri. The erythrodermia was refractory to all treatments, but it disappeared following radical operation of the carcinoma. The author thinks that this fact deserves special consideration, as it makes it appear probable that an etiologic connection exists between carcinoma and the skin disease.

Prolonged Irradiation of Gynecologic Carcinomas.—Reichenmiller employed prolonged irradiation in advanced carcinomas of the cervix uteri and in extensive recurrences of uterine carcinomas. Nearly all these patients first received radium treatment according to the Paris or Stockholm method. The roentgen irradiation, according to Coutard's method, was instituted four weeks after completion of the radium series. The ray quality was such that 17 mm of copper absorbed one half of the rays. Filtration was done by means of the Thoräus filter. The focal distance was 60 cm. The dosage was measured continuously on the skin of the patient with the aid of a special dosimeter. Thus the entire active dosage, including the reflected irradiation from the tissues, was measured. The minute dose was 4 roentgens (action dosage). The irradiations were given daily alternately on the abdomen and on the back. The abdominal fields received a daily action dosage of 250 roentgens, the back fields a dosage of 200 roentgens. Lead and rubber protectors prevented undesirable scattered irradiation. The irradiations were continued until the desired radio-epidermitis sicca developed, which usually

required about four weeks, or until each field had received an active dosage of from 3,000 to 3,500 roentgens. The reaction became manifest as a slight itching and as a uniform redness and swelling of the irradiated skin, or as thickly strewn, small, light red dots. After several days a superficial, dry exfoliation set in, and a slightly tanned epidermis resulted. By the time the skin reaction set in, the dosage at the carcinoma was from 3,000 to 3,500 roentgens. Cachectic patients did not tolerate this treatment, and consequently the author advises against it in such cases. However, in patients who were in good general condition the treatment was effective and the remnants of carcinoma which were not destroyed by the radium irradiation, disappeared. Diarrhea generally developed as the first sign of the ray reaction, but it subsided without causing loss of weight. Roentgen intoxication and cardiovascular disorders did not occur. A slight lymphopenia often developed toward the end of the irradiation but disappeared again within three months. Together with the skin reaction, colpitis supervened and in some instances led to exfoliation of the vaginal epithelium. The urine had a slight albumin content, owing to changes in the bladder, but after three months most of these changes had disappeared.

Jurnal Po Rannemu Detskomu Vozrastu, Moscow

Chickenpox in Nourlings. A. V. Troetskiy—p 391

*Symptom Complex and Rational Treatment of Melena Neonatorum. I. A. Shtern—p 396

Septic Conditions of New-Born—Gok-Smirchek reports 87 deaths among 3,750 new-born infants of the obstetric clinic of the Moscow Scientific Institute for the Protection of Motherhood. The premature infants and those weighing below 2,500 Gm contributed 25 per cent of this mortality, infants weighing between 2,500 and 3,000 Gm contributed 173 per cent, while full term infants and those weighing above 3,000 Gm contributed 04 per cent. The causes of mortality in order of their frequency were always considered to be (1) congenital debility, (2) birth injuries, (3) septic infections and (4) syphilis. Postmortem examinations, however, demonstrated that, in the greater number of cases clinically designated congenital debility, death actually resulted from septic conditions. The author isolated a hemolytic streptococcus from the nasopharynx of the new-born in 393 per cent and from both mother and infant in 21 per cent of the cases. Evidently, a number of infants derived the infection from the attendants and the environment. The author concludes that septic infections develop with greatest frequency in premature and congenitally weak infants. The mortality from these conditions was likewise highest in this group. The full term, well developed children more frequently resisted the infection but became carriers. Chilling, poor nutrition and the lack of fresh air and of actinic rays were capable, however, of causing morbidity by reducing their resistance. The most effective measures in combating mortality of the new-born are those directed to prophylaxis. The author advocates for the prenatal stage improvement of the living conditions of the pregnant woman and proper instruction particularly directed against late coitus. The intranatal prophylaxis is summed up in strict asepsis during delivery and at the first toilet of the infant. For postnatal prophylaxis the author advocates properly constructed infants' rooms, sufficient incubation, abundance of light and sunshine, special rooms for the care of children, linoleum covered floors, a separate laundry, and separate disinfecting closets. With the view of eliminating streptococcus carriers, the author insists on systematic examinations of the nasopharyngeal discharges of the attendants and on the isolation of such mothers and infants as are found to be sick or to harbor streptococci.

Melena Neonatorum—From the material of the Moscow obstetric clinic, Shtern reports an incidence of true melena in 15 of 30,627 births. He is inclined toward the theory of toxic origin on the basis of constitutional defect in the vascular tissues, particularly of the capillaries of the gastro-intestinal tract. He found occult blood in feces in 51 per cent of ninety-three normal new-born infants, suggesting occult bleeding from the gastro-intestinal tract. Low hemoglobin and a low erythrocyte count are characteristic of true melena and

differentiate this condition from cases of spurious melena. Coagulability of the blood is only relatively retarded during the course of the disease and returns to normal on recovery. The author treated six patients with injections of placental blood serum, a method suggested by Serdyukov for the treatment of hemorrhage. From 15 to 5 cc of the serum is injected according to the severity of the case. A recurrence of bleeding is treated by a second injection of 5 cc. No untoward symptoms from such injections were observed. Of the six patients treated by this method, only one infant with valvular disease of the heart died. Of nine previous patients treated by calcium and gelatin injections, three died. The rationale of placental serum injections is based on the fact that it exerts a vasoconstrictor effect on the capillaries and contains hormones, particularly epinephrine, and certain serum albumins. The author suggests the prophylactic use of the serum in proper cases. The loss of blood calls at the same time for adequate supply orally or by hypodermic injection of physiologic solution of sodium chloride.

*Investigations on Mechanism of Albuminuria. J. Bing—p 415

*Studies on Immigration of Dextrose into Red Blood Corpuscles in Man. T. Bjerring—p 425

Fractures of Lower Jaw. O. Bjerrum—p 437

Albuminuria—Bing's investigations confirm the assumption that in albuminuria a filtration of serum proteins occurs through degenerated glomeruli, probably without elimination in the tubuli. The elimination of albumin and globulin is parallel with the filtration, the protein content of the glomerulus filtrate probably being constant in constant blood conditions and changing with changes in the serum proteins. The degree of the glomerulus lesion is also assumed to be significant in the albuminuria.

Immigration of Dextrose into Blood Corpuscles in Man—Bjerring's experiments show that human blood corpuscles under physiologic conditions contain dextrose and that the membrane of the blood corpuscles is permeable to this substance when the corpuscles are in their natural milieu, the plasma. Allowing for the difference between the "rest reduction" of the blood corpuscles and the plasma, the dextrose is under physiologic conditions apportioned between the red blood corpuscles and the plasma according to the laws of diffusion.

Relation of Living Leukocytes to Iso Agglutination. I. Wallgren—p 891

Current Potential in Circulation and Significance in Pathogenesis of Hypertension. F. Leiri—p 901

Gastric Tetany—Langenskiöld's material consisted of ten cases of certain or suspected stenosis of the pylorus or intestine, including one with gastric tetany, also a case of parathyroid tetany and a case of tetany of pregnancy. He concludes that the total calcium content of the blood does not have the same significance in the pathogenesis of gastric tetany as in the majority of other forms of tetany. The guanidine found in the urine in several instances is thought not to have originated in the alimentary canal but is rather assumed to be a sign of deficient protein metabolism and perhaps to be regarded as a result of tetany or a phenomenon coordinated with the other symptoms of this disturbance.

THE USE OF DIGITALIS OTHER THAN IN THE TREATMENT OF CARDIAC DECOMPENSATION

HENRY A. CHRISTIAN, M.D.
BOSTON

We of the present generation of physicians are all too apt to discount the medical wisdom of our predecessors instead of realizing that they were keenly wise clinicians who, even though they possessed far fewer instruments of precision and laboratory tests than have we, were critical observers of patients and knew in what we like to call an empirical way much that we have been unable to improve on. One of the difficult tasks of modern medicine has been to find a scientific reason for the action of many therapeutic procedures developed by our medical forebears.

The use of cod liver oil is an excellent example of this. Many generations of clinicians prescribed cod liver oil because they witnessed its efficacy, and they found out what conditions it benefited most strikingly. Many were the theories advanced in explanation of its effectiveness, some of them weirdly complex. Only recently has knowledge of vitamins started investigators on the probably correct explanation of the action of cod liver oil. Fortunate it has been for many patients that physicians continued to use cod liver oil just because observations showed it to be beneficial, instead of saying "Until we know in a scientific way just how it acts, we will not use it."

Somewhat similar conditions have prevailed concerning digitalis. Withering showed the striking effectiveness of digitalis in treating dropsical conditions, although he knew nothing of the mechanism of its action. For many years Withering's wise directions of 1785 in regard to the use of digitalis were disregarded, and for a long period of time after Withering there was an almost complete abandonment of Withering's criteria of the therapeutic use of digitalis. Later such pharmacologic knowledge as had been obtained, instead of improving the clinical use of digitalis, aroused such fear of the toxic actions of digitalis that physicians became afraid to give it to patients in dosage needed to produce adequate therapeutic effects. Then came more complete knowledge of the pharmacology of digitalis and a return to the therapeutic dicta of Withering with an ending of those therapeutic tears that had inhibited us from obtaining good digitalis effects in our patients. Digitalis regained its place of great usefulness in the treatment of cardiac decompensation with later a tendency toward very large dosage from which recently there has been a recession to more moderate dosage

with, in my judgment, a definite improvement in the management of cardiac decompensation.

Our predecessors in the practice of medicine made use of digitalis other than in the treatment of cardiac decompensation. Withering, of course, considered digitalis a diuretic. There has been much discussion as to whether digitalis has any diuretic action apart from its effect in improving renal circulation as part of a general circulation improvement in patients with cardiac insufficiency. Some have denied any direct diuretic effect, while others have claimed that digitalis had a diuretic action apart from any effect on the general circulation. Recent observations in my laboratory by Dr. E. A. Bartram on normal dogs in which digitalis was introduced into the renal artery show that digitalis does cause a diuresis. However, there is no doubt that the clinical efficiency of digitalis as a direct diuretic is slight, while as an indirect diuretic in the presence of cardiac decompensation digitalis often is very effective, and certainly as a diuretic under these conditions it is most useful.

Many of the older practitioners regarded digitalis as a heart "tonic" and gave it in small doses to patients in whom there were no definite signs or symptoms of cardiac decompensation. This use was based either on simple clinical experience with patients or on imperfect knowledge of the pharmacologic action of digitalis. In recent years such utilization of digitalis seems largely to have been discontinued. When I was a medical student, over thirty years ago, I was taught to use digitalis only after signs and symptoms of cardiac insufficiency developed, but not to give it when merely evidences of such pathologic conditions as hypertrophy or murmur were detected. Recent books seem to continue such teaching. As examples of this White¹ says "There are three chief indications for the need of digitalis therapy: (a) congestive heart failure, with or without auricular fibrillation, auricular flutter or heart block, (b) auricular fibrillation or auricular flutter with rapid ventricular rate, when quinidine sulphate alone is not administered at once, and (c) as a therapeutic test when it is uncertain whether or not there is a slight degree of congestive failure, or perhaps as a means of warding off impending failure, as in the case of old people with dyspnea on exertion, of victims of chronic pulmonary emphysema with a higher degree of dyspnea than is readily attributable to the lung condition alone, and of patients with pneumonia." In Osler-McCrae,² under treatment of myocardial insufficiency, the statement is made concerning digitalis that "the indication for its use is insufficiency of the heart muscle, especially when auricular fibrillation is present, it should not be given when there is good compensation," and under treatment

¹ White, P. D. Heart Disease. New York, Macmillan Company, 1931.

² Osler, William and McCrae, Thomas. Principles and Practice of Medicine. New York, D. Appleton & Co., 1930.

of chronic valvular disease of the heart, "a common error is to administer drugs such as digitalis, on the discovery of a murmur or of hypertrophy" Cecil³ seems to make no reference to the use of digitalis in heart disease except under the heading of treatment of cardiac failure, and the same is true of Musser.⁴

Our professional ancestors, as already stated, had what they called a "tonic" use of digitalis, using it in small doses as a cardiac "tonic." In recent years I myself have come to the belief that digitalis has a worthwhileness in treatment entirely apart from its undoubted value in the control of cardiac decompensation. This belief does not depend on any assumption that digitalis is a cardiac "tonic" in the usual sense of the word "tonic" but on the belief that digitalis helps to inhibit cardiac hypertrophy and to retard some of the aging process of the myocardium.

CARDIAC ENLARGEMENT AND CARDIAC EFFICIENCY

Before discussing further these uses of digitalis, I should diverge from my main topic to give my ideas in regard to the relationship between cardiac enlargement and cardiac efficiency. These may be stated in the thesis: Cardiac hypertrophy instead of being a beneficial process, is an injurious influence on cardiac function, the heart once enlarged, is already on its way to eventual decompensation, to retard hypertrophy is to prolong cardiac efficiency.

These statements seem in opposition to what is known of muscle function and the effects of training. Hypertrophy of the heart muscle has been considered to be a way of increasing heart function, because such seems to be true of skeletal muscle. If the arm muscles, for example are exercised these muscles enlarge and acquire greater strength. If the exercise is decreased, these muscles decrease in size and lose in strength. Why should not the same be true of heart muscle, in many respects so similar in structure to skeletal muscle? Briefly, the answer is that heart muscle surrounds a cavity and the effect of its contraction is to empty a cavity, conditions entirely different from those pertaining to skeletal muscles. When heart muscle hypertrophies, the cardiac cavities enlarge and contain more blood. The result is more work for the heart muscle to do. More work causes more hypertrophy and still larger cavities with still more of a load of work. It is the stretching of the muscle by an increased load that is the stimulus to hypertrophy. Stretching cardiac muscle enlarges the cavity surrounded by the muscle. For a time hypertrophy keeps in balance with increasing load resulting from enlarging the cardiac cavities. In the heart, however, with muscle forming the wall of a cavity, soon there is a disproportion between thickness of muscle wall and size of surrounded cavity and a lag ensues in hypertrophy in relation to the work demanded of the myocardium, followed by a decreasing efficiency of heart function.

Clinical observation has taught that with few exceptions the enlarged heart rarely recedes in size and that sooner or later the enlarged heart shows signs of inefficiency. It may be taken as a clinical dictum that cardiac hypertrophy with rare exception is the first evidence of cardiac failure, though it may long antedate any symptoms or signs of cardiac insufficiency. If one considers that type of heart disease which is most frequent in adults, so-called chronic myocarditis, chronic

nonvalvular heart disease or chronic myocardial insufficiency, whatever term one prefers to use for this condition, it will be found that the foregoing statement is unqualifiedly true.

If, then, as I believe, cardiac enlargement is functionally harmful, intelligent therapeutics will seek to retard it. It is generally believed that increased demand on cardiac function serves to increase cardiac enlargement, and so clinicians advise patients with enlarged hearts to decrease their physical exertion. Can anything else be done in the way of treatment? I believe that just here digitalis has a definitely desirable effect, and if given daily in moderate dosage it will retard cardiac enlargement and delay the appearance of symptoms and signs of cardiac insufficiency. Consequently I advise patients in whom I find enlargement of the heart to decrease physical exertion and to take continuously from 0.1 to 0.15 Gm of digitalis leaves twice daily, unless this amount causes toxic symptoms, as occasionally it does. If that happens, the dose is reduced to a point at which no toxic symptoms appear. Digitalis for these patients is continued throughout the remainder of life. The optimum dose is that just below the one which eventually produces toxic manifestations, a dose to be determined by the method of trial and error.

USE OF DIGITALIS

If cardiac insufficiency has developed to a point to produce symptoms and signs marked enough to interfere with the individual comfort and activities, it is said that cardiac insufficiency has developed or that the heart is decompensated. Rest and digitalis is the practically universally instigated therapeutic management of such cases. In a large percentage so treated, symptoms and signs of cardiac insufficiency very largely disappear. With return to a greater degree of physical activity, sooner or later a return of the same symptoms and signs is to be expected. Clinical experience indicates that, if to such patients a daily ration of digitalis, short of toxic effects, is given, this return of evidences of cardiac insufficiency will be delayed. Consequently it has become a quite general practice to give such patients digitalis continuously in amount just short of toxicity, the proper amount approximating 0.15 to 0.25 Gm daily of powdered digitalis leaves, the exact amount being determined by the method of trial and error, some patients tolerating more and others less than this daily ration in the sense of being just short of toxicity. This elsewhere I⁵ have termed the continuation treatment with digitalis.

Now if digitalis, thus used as a continuation treatment, is helpful under the circumstances just enumerated, it is reasonable to suppose that, if given in this way prior to the development of symptoms and signs of cardiac insufficiency, development of these symptoms and signs might be delayed. My own clinical experience seems to be in accord with this idea, and so I have come to give digitalis in this way to patients in whom I can detect evidences of cardiac disease, particularly cardiac enlargement. It does seem as if cardiac enlargement is retarded and that these patients are capable of greater activity without having symptoms or signs of cardiac insufficiency than are patients otherwise similar not receiving digitalis.

There are certain individuals in whom, although there is no detectable evidence of cardiac enlargement, one can feel quite certain that sooner or later enlarge-

ment of the heart will take place. The most numerous in this group are individuals with hypertension and next in frequency come those who have developed a diastolic murmur of some sort or who, with a past history of rheumatism, show a systolic murmur without any murmur in diastole. The query naturally occurs in light of what I have just been saying, Why not give digitalis to such individuals?

Certain observations of pharmacologists investigating digitalis have a bearing on this suggestion. At one time it was believed that digitalis would cause cardiac hypertrophy, but many experiments have shown that this did not occur. Cloetta noted that animals receiving digitalis over long periods of time had even lighter hearts than those receiving no digitalis. Furthermore, he found that, if aortic insufficiency was produced, animals subsequently given digitalis had hearts both smaller and more efficient than did animals with similar aortic lesions not receiving digitalis. Here is experimental evidence in favor of the clinical thesis that I have just enunciated in regard to beginning digitalis even prior to the development of hypertrophy in those patients in whom hypertrophy may be expected to develop.

Observation has shown that in the aging process the heart muscle loses water. Other observations show that one effect of digitalis is to increase hydration in heart muscle. This points to a probable therapeutic effectiveness of digitalis for elderly patients not to be expected in the young. Heart disease due to myocardial insufficiency is most frequent in the later decades of life. Clinical experience points to a particular usefulness of digitalis in just this group of individuals, those past middle life (40 to 50), with cardiac enlargement without valve lesions, not yet having symptoms or signs of cardiac decompensation. Competent observers believe further that in elderly people with no evidence of cardiac enlargement but in whom circulatory efficiency is lessening, digitalis increases heart efficiency, and here digitalis possibly may be said to have a definitely "tonic" effect, presumably increasing the hydration, which has decreased in the aging process.

Pharmacologists have demonstrated a certain automaticity in the regulation of digitalis effects that help in the treatment of patients with cardiac enlargement. Digitalis before it exerts any digitalis effect, is fixed in the heart muscle. After fixation in the heart muscle it is split up into an inert carbohydrate and a substance that produces a digitalis action. This fixation varies directly with the concentration of digitalis circulated to the heart muscle and with the bulk of the heart muscle but indirectly with the rate of circulation through the muscle. These laws of digitalis action influence the effectiveness of digitalis therapy. As the heart enlarges, all other factors being unchanged, a given dose of digitalis has an increasing effectiveness in ratio to the increasing bulk of the myocardium. As the myocardium loses in efficiency, the circulatory rate in the coronary system of vessels is slowed. As a result of this more digitalis is fixed in the heart muscle fibers and this causes an increased digitalis action. In other words within certain limits, an automatic increase in digitalis action occurs under just those circumstances that would need a greater digitalis action and that without any increase in size or dose. As heart action improves, circulatory rate through the myocardium accelerates and fixation of digitalis decreases, thus bringing about a lessened effect from a given dosage than would be the case were there not this relationship. In other words when there is more need for digitalis,

digitalis is proportionately more effective, and when the need decreases, the same dose of digitalis has less effectiveness. This saves the clinician from the necessity of continuously changing digitalis dosage to meet changing function of the heart muscle.

CARDIAC ENLARGEMENT OR DILATATION

During the preceding discussion I have used cardiac enlargement and cardiac hypertrophy interchangeably. I have made no mention of dilatation of the heart. Whenever the heart enlarges or hypertrophies, the cavities of the heart enlarge and this is dilatation. Dilatation without hypertrophy practically does not occur. What clinically is considered acute dilatation of the heart is either a paroxysm of fibrillation or flutter or is actually a decrease in heart size with an accompanying decreased systolic output of blood. It seems to me, for the reason given, desirable not to use in clinical discussions the term dilatation of the heart, but to speak only of enlargement or hypertrophy.

VALVULAR HEART DISEASE

What has been said about nonvalvular forms of heart disease applies, too, to valvular types of heart disease except that since valve lesions occur chiefly in younger people, in whom heart muscle has not lost water, the action of digitalis on heart function is less effective than when given to older persons. Also, as valve lesions introduce an unchangeable mechanical factor decreasing heart efficiency, again not so striking an improvement is to be expected from giving digitalis to these patients. However, since there is no harm caused by giving digitalis, it is reasonable to give it, too, in valvular heart disease as just advised for nonvalvular heart disease both prior to and subsequent to the appearance of symptoms and signs of cardiac decompensation. It seems probable, however, that here it will not be as useful as with nonvalvular forms of heart disease.

LONG CONTINUED DOSAGE

Digitalis for the conditions just being discussed is continued over very long periods of time. Obviously, if a drug is to be taken daily over long periods of time, it is essential that the drug has no harmful effects, direct or indirect, that it has no habit-forming qualities and that from continuous use it does not lose its effectiveness. There is no pharmacologic or clinical evidence that any of these things happen. Repeatedly have I seen the patient who has been taking a daily dose of digitalis for weeks and months respond to an increased dose indicated by reason of developing evidences of cardiac decompensation, in just the same way as a patient with similar evidences of cardiac failure who had received no previous digitalis therapy.

If one will stop to think of the way digitalis acts, it will be seen to be an ideal drug, pharmacologically, for long continued dosage. Digitalis given by any route or dosage reaches the heart muscle, where it is promptly fixed or bound. In a short space of time it commences to be split within the muscle into a part that has digitalis action and an inert part. This splitting is a gradual process, long continued, very slowly decreasing in the degree of digitalis action on the heart muscle. Before one dose has ceased to act another can be given, which in its turn will be fixed and split and continue a digitalis effect. It is entirely possible on account of this way of action to space properly sized doses of digitalis so as to maintain a digitalis action throughout the twenty-four hours with but little fluctuation from hour to hour in the intensity of that action and to continue it prac-

tically indefinitely from day to day by suitable doses not closer together, let us say, than twelve hours. Could there be a more ideal mechanism for maintaining a therapeutic effect over very long periods of time? In this respect digitalis has a part almost like the replacement therapy of thyroid gland substance in myxedema, insulin in diabetes mellitus and liver extract in pernicious anemia, for all of which physicians say to their patients you must continue taking this daily so long as life lasts.

Peter Bent Brigham Hospital

TECHNIC OF NONSURGICAL DRAINAGE OF THE BILIARY TRACT

JOHN RUSSELL TWISS, MD

NEW YORK

Recent developments in the study of biliary tract disease have given added importance to nonsurgical drainage of the biliary tract. This description of technic, based on the procedure described by Lyon¹ in 1923 and including recent improvements, is given because the drainage can have no diagnostic or therapeutic value unless it is properly performed. The method described has proved satisfactory in more than 3,000 drainages which have been done as part of the routine in the Medical and Surgical Gall Bladder Clinic of the New York Post-Graduate Hospital.

In the performance of a drainage, the relaxation and comfort of the patient are important. A quiet room with not more than one patient gives best results. Reassurance on the part of the operator is helpful if the patient has not had the tube before. He is instructed to swallow the tip of the tube in the same way as food. Before he does so, the tip is moistened by water or oil. After the tube tip has passed the glottis, as indicated by a tug, which can be felt by the operator, it can be passed quickly into the stomach without further swallowing.²

The duodenal tubes used in this clinic are the Levin catheter-tip and the metal-tip models such as the Rehfuß, Lyon, and one that I³ have recently described. In our experience the metal-tip models shown in the illustration have proved more satisfactory for the average patient. The terminal weight allows more certain passage of the tube into the duodenum and tends to prevent its regurgitation into the stomach. A fresh resilient tubing is essential for good results. The duodenal tube, when not in use, should be hung in a dark closet rather than coiled. The metal tips when corroded should be replaced.

Our tube has proved useful, especially in patients in whom drainage by other types of duodenal tubes has been unsuccessful. The features of this tube which have been described include the use of a larger tubing, a metal tip of smaller diameter, and a terminal weight which acts as a leader in drawing the bucket into the

duodenum and tends to hold it there. When drainage is to be repeated, the markings of the tube provide information as to what length of tubing was used to procure bile. For this purpose there is a numbered scale from the fourth, or 80 cm, mark to the two-ring mark, the number at the lips of the patient during the drainage is recorded on his chart.

For drainage the patient is instructed to report in the morning with an empty stomach. If a previous drainage has proved unsatisfactory, a preliminary course of bromides or belladonna is given over a period of three days, including the morning of the drainage. For sensitive throats and to prevent gagging, a throat spray of 4 per cent cocaine hydrochloride usually gives relief. Retching or excessive salivation after the tube is in the stomach is controlled by the injection through the tube of a solution of 30 grains (2 Gm) of triple bromides or one-fiftieth grain (13 mg) of atropine sulphate. These measures also relieve pylorospasm, which is indicated by failure of duodenal intubation.

The passage of the tube from the stomach into the duodenum affords the greatest possibility of difficulty. This may be done with the patient in the sitting position or with the patient lying on the right side. By either

Types of duodenal tube tips A, Rehfuß, B Lyon, C author's D, Levin

method a gastric specimen is procured after the tube has been passed, the patient remaining in the sitting position, to approximately the two-ring mark. The stomach is lavaged with hot water. The tube is then withdrawn nearly to the one-ring mark.

The timing of the passage of the tip through the stomach is essential to allow engagement of the tip in the pylorus and to prevent looping. The tube is best introduced by the patient, if cooperative. He is given a watch and shown a marker on the drainage tube. This marker is placed at the fourth mark if the sitting position is used, at the three-ring mark if the patient is lying on the right side. For the sitting position the tube may be pushed down at the rate of one inch a minute, for the prone position one inch every two minutes. Our usual procedure is first to attempt introduction in the sitting position. If this is unsuccessful in obtaining bile even after a stimulation with hot water, the tube is withdrawn to the one-ring mark and passed with the patient lying on the right side.

Fluoroscopic control of duodenal intubation as described by Morgenstern⁴ has been of value in difficult

This work has been aided by a grant from the Oliver Rea Fund. From the Departments of Medicine and Surgery of the New York Post-Graduate Hospital.

¹ Lyon, B. B. V. Non Surgical Drainage of the Gall Tract, Philadelphia, Lea & Febiger, 1923.

² The complete equipment includes drainage tubes, a 1-ounce bulb syringe, ten 2-ounce wide-mouth bottles with labels and corks (for bile specimens), pus basin, a 32 ounce graduate, drinking glass, safety pins, a dozen paper napkins, a throat spray containing 4 per cent cocaine hydrochloride, a 16 ounce bottle of 50 per cent magnesium sulphate, a 2 ounce bottle of olive oil, 4 ounces of triple bromide mixture, a vial of tablets of atropine sulphate, 1/100 grain and a vial of congo red paper. A large ring stand provides an adjustable tray for holding the drainage bottle. A clamp on the stand secures the drainage tube.

⁴ Morgenstern, Morton. A Simplified Procedure for the Introduction of a Tube into the Duodenum, J A M A 97: 175 (July 18) 1931.

patients For this purpose our own tube or that of Levin is used The patient stands before the fluoroscope with the tube in the stomach, facing the operator, who is seated The tube is withdrawn until it is seen to hang vertically in the cardiac end of the stomach The patient is then instructed to swallow the tube slowly and to breathe deeply, at the same time the operator pushes the greater curvature of the stomach upward with the left hand and directs the tip toward the pylorus with the right hand By this means the tube can frequently be introduced into the duodenum in a few minutes The tip can easily be seen looping upward and over into the duodenum in the right upper quadrant This action is best visualized with the metal tip The injection of an ounce of very hot water is at times of assistance in passing the tip through the pylorus

When no fluoroscope is available, the position of the tube in the duodenum may be checked in several ways The character of fluid aspirated may be of assistance Gastric contents are watery, are turbid, contain flakes of mucus, and turn green if bile stained Duodenal contents are usually clear, homogeneous, more viscid, and golden yellow if bile is present A stimulation with hot water is sometimes necessary to obtain bile Gastric contents containing free hydrochloric acid turn congo paper blue This reaction usually disappears in duodenal contents Air injected by syringe into the stomach usually returns promptly, if the tip is in the pylorus or duodenum the return of air is retarded

After the duodenum has been entered, 1 or 2 ounces (30 or 60 cc) of clear golden yellow bile usually drains by siphonage After this an ounce of warm 16 per cent magnesium sulphate is slowly injected, allowed to remain two minutes and then siphoned off before the bile specimen is collected Two similar injections of 25 per cent magnesium sulphate are given to obtain further specimens If dark concentrated bile is not obtained after three injections of magnesium sulphate, an ounce of warm olive oil is instilled and allowed to remain in the duodenum ten minutes after which further specimens are obtained If at any time the flow of bile ceases this may be due to plugging of the tip by mucus The tip may be out of position, having gone beyond the duodenum or regurgitated into the stomach

Specimen bottles of bile are numbered consecutively, beginning with the gastric contents Each is designated according to the stimulant used as described elsewhere Chemical analyses are done as indicated Usually about 2 ounces of bile is obtained after each stimulation, the total amount of bile being approximately 12 to 15 ounces (350 to 450 cc)

Examination of bile specimens is recorded by a check system on a special drainage sheet The volume of each specimen is noted together with its appearance as to color, viscosity, turbidity, and amount of sediment A sample of sediment is procured by means of a pipet from each bottle and examined microscopically A quantitative estimate is made of such elements as clear or bile-stained pus cells, columnar epithelial cells, crystals of cholesterol or calcium, calcium bilirubinate, bile-stained mucus and debris

Sterile drainages must be done under certain precautions A separate room is used for this purpose All containers, equipment and solutions are sterilized

before use The patient is instructed to gargle repeatedly before the drainage, using a solution of 1 drachm of silver nucleate to a half glass of sterile water The patient is cautioned against swallowing saliva, and the gastric lavage is performed with hot sterile water In taking a culture the terminal piece of rubber tubing is removed temporarily from the straight glass tube, or from the arm of the Y tube which has not been used for injecting fluid The sterile glass tip is then flamed before bile specimens are collected A few cubic centimeters of sterile water is first run through the tubing and cultures are taken in broth to check sterility Five cubic centimeters of each type of bile is collected in a plain sterile test tube for plating purposes By this technic it has been possible to obtain sterile cultures in a large proportion of cases and to obtain a single organism repeatedly in the same patient

SUMMARY

1 Recent investigation has confirmed the importance of duodenal drainage as a means of investigating the biliary tract

2 Proper performance of this procedure is essential for the results to have any value in the diagnosis or treatment of biliary tract disease

3 The clinic routine as outlined has proved satisfactory in more than 3,000 drainages

65 East Fifty-Fifth Street.

THE EFFECTIVENESS OF COMMERCIAL DIPHTHERIA TOXOID IN ACTIVE IMMUNIZATION OF INFANTS

JOSEPH GREENGARD, MD

CHICAGO

Diphtheria toxoid as an antigen for the production of active immunity has proved very effective¹ The report of a series of 100 infants so treated was published in 1931² In this group, 98 per cent were rendered negative to the Schick test, in these cases the production of immunity was quite rapid, the greatest proportion showing a negative Schick test within two weeks of the last dose of toxoid and complete immunity being produced in six weeks in practically all In this group the technic of immunization consisted in the hypodermic injection of two 1 cc doses of toxoid, spaced at a three weeks interval in thirty-six and at a one week interval in eighty-one The group in which the short interval was used apparently showed just as good results as the one with the longer interval A commercial toxoid was used, all of which was produced by the same manufacturer

In continuing the immunization program during the past year, a batch of toxoid was purchased from another manufacturer In the group of babies immunized with this particular material, the results seemed less favorable Immunization seemed to be slower in appearance and the number of failures greater It was therefore decided to place several groups of infants on various types of commercial toxoid to determine whether or not there might be some variation in antigenic potency in

the material marketed. The groups were taken in rotation as positive Schick tests were obtained, with no attempt at selection. The technic was the same in all infants and was identical with that used in the series reported with the exception that a one week interval was used in all cases. Two distinct series were run with the toxoid that gave poor results, separate packages being purchased for each series, and immunization carried out in the second series six months later than that of the first to rule out the possibility that a single

mately 97 per cent completely immunized, and the immunity here also was rapid in appearance, the results being comparable to the first series reported.

The great difficulty in achieving absolutely parallel series of cases in clinical investigation is readily apparent. In this connection, age is of considerable importance in comparing the effectiveness of an antigen, for it has been shown that the ability to produce antibodies increases with age.⁵ The age distribution of the various groups is shown in table 2. It will be noted that the groups in which 100 per cent immunity was obtained (thirty-nine cases) in general tended to be composed of older infants than group 3 series a, in which 85 per cent were rendered Schick negative. On the other hand, group 3 series b, with only 80 per cent rendered immune, gave very nearly the same age distribution as the infants in groups 1 and 2, which yielded 97 per cent immunized, 66.6 per cent below 6 months in the former and 64.2 per cent below 6 months in the latter. The preponderance of older infants in groups 4 and 5, however, may be a factor in the complete lack of failures noted here.

The age distribution of the infants in whom the Schick test remained persistently positive is of interest in this regard. It will be noted that all but one of these twelve infants were under 6 months of age, a finding in agreement with the statements in the literature that young animals form antibodies badly. It is also noteworthy that with a potent toxoid most infants under 6 months of age can be rendered Schick negative rapidly.

TABLE 3—Age Distribution in Cases Persistently Positive

1 M N	16 days	7 M M	3 months
2 M A T	3½ weeks	8 F B	4 months
3 B B	2 months	9 M L	5 months
4 J Mc	2½ months	10 B A	5 months
5 B H	3 months	11 J S	6 months
6 M B	3 months	12 D Mc	21 months

The variability in antigenic potency of various batches of diphtheria toxoid is of great importance. It is obvious that considerable discrepancy in the results of immunization by the use of toxoid will appear when material of inferior antigenic potency is being marketed. Perhaps the outstanding advantage of this agent is the fact that a material of high antigenic potency is made available which is nontoxic, irreversible and very resistant to changes in temperature, aging and the like. Ramon⁶ has pointed out the ease and accuracy of the determination of antigenic potency of diphtheria toxoid by the flocculation test. Together with Nélis⁷ he has demonstrated the agreement between flocculation and clinical tests for antigenic potency. In a group of 269 children vaccinated with anatoxins of 7 and 4.5 units, respectively, 80 per cent were rendered Schick negative, and in 293 parallel cases in which anatoxins of 16 and 12.5 units were employed, 94.2 per cent were rendered Schick negative in from twelve to fourteen days. These results are strikingly similar to those noted in our babies.

In general, it may be said that the five groups of infants, while differing from one another slightly in some respects, are nearly enough parallel to act as test groups for the various toxoids used. The discrepancy

lot of ineffective material might have been used. The toxoid was purchased in the open market and was used up quite rapidly, in every case within almost a year of the expiration date as given on the package.

The results are given in table 1. It will be noted that in the five brands of toxoid used one, designated as 3, was definitely less effective than the other four. In the first series of twenty-eight cases, four, or 14.2 per cent remained persistently positive. Of the twenty-four infants completely immunized, the interval between the last dose of toxoid and the ensuing negative Schick test was over six weeks in seven cases and as long as twenty weeks in one. In this connection it must be borne in mind that, in an individual who has received a primary antigenic stimulus, even minute secondary antigenic stimuli, such as the tiny amount of toxin used in a Schick test, may produce considerable amounts of antitoxin (Glenny,³ O'Brien⁴). It is therefore quite possible that some of these infants who became negative after ten, twelve or twenty weeks may have responded to the repeated small doses of Schick toxin with suffi-

NEW HAVEN, CONN

In a previous paper¹ were reported studies of the laxative effects in healthy men of wheat bran and an acid-extracted product called "acid washed bran." These studies showed (a) that wheat bran and "acid washed bran" possess demonstrable laxative power when tested on healthy men subsisting on known carefully controlled diets, (b) that there is a quantitative relationship between the fiber content of the diet and the degree of laxation prevailing in healthy men, and (c) that the laxative value of bran and bran products may be estimated fairly accurately from the fiber content. In view of the objections on the part of certain clinicians² to the use of bran as a laxative, it becomes of importance to determine the limitations, if any, of these reactions, which were the results of studies on healthy men.

It was believed that a study of the actual laxative performance of patients suffering from constipation when subsisting on diets of known fiber content would yield data of value. It is conceivable that many such patients are actually ingesting rations too low in roughage content and erroneously assuming that their roughage intake is adequate. There is the possibility that many cases of constipation are due to this cause and would show satisfactory laxation when the fiber intake was made adequate by ingestion of bran or other fiber-rich material. It is also conceivable that certain individuals with pronounced tendency to constipation are characterized by a particular bacterial flora or the presence of cellulase (?) capable of decomposing ingested fiber to an unusually high degree, and, as a result these individuals actually lack fibrous roughage sufficient to stimulate normal eliminatory processes by the time the food residues reach the rectum. Such individuals might be regarded as requiring a higher fiber minimum than that found for the healthy men on whom the earlier studies were made. Careful observations of the degree of laxation prevailing when on diets of known fiber content and tests of bran and bran products in such cases should yield much information suggesting the limitations of the results of the previous study and the validity of one or more of the possible explanations of constipation just given. The chief objective of the present investigation was the performance of such tests on patients suffering from constipation.

The expenses of this research were defrayed in part by a grant from the General Electric Corporation, New York.
From the Department of Experimental Chemistry and of Internal Medicine, Yale University School of Medicine.

PLAN OF INVESTIGATION

Patients—Six men, all of whom had suffered from constipation for a considerable period, were secured for this study. Brief summaries of clinical data of interest are here presented.

Mr J., a medical student, aged 25, had suffered from constipation for four or five years. He averaged about nine stools in two weeks and was in the habit of taking a double dose of seidlitz powders about once in two weeks when especially constive. He ate more fruit and vegetables than the average person and stated that, if he ate nothing but fruit, his bowels would be regular. When constive, he suffered only from lassitude and from rectal spasm due to straining.

Mr M., a medical student, aged 23, had been troubled with constipation for years. He averaged about five small stools a week but was able to go four or five days without a stool without exhibiting any symptoms. He ate very little fruit and vegetables, his diet consisting chiefly of meat, cheese, milk and bread.

Mr E., aged 40, unemployed for some time, had suffered from constipation and indigestion for twenty years. During the past year the condition had become progressively worse. He had been taking various cathartics irregularly over a period of years. When constive, he suffered from epigastric distention, the feeling of a "lump in the stomach" and heartburn. He had taken a great deal of sodium bicarbonate for the gastric distress. Roentgenograms of the upper gastro-intestinal tract were negative. He ate but little fruit and green vegetables.

Mr F., a laboratory assistant, aged 51, had been troubled with constipation for about fifteen years. He had suffered from occasional pain in the lower part of the abdomen and at infrequent intervals had a little indigestion. Over a period of years the patient had taken an enema three times a week. A series of roentgenograms of the gastro-intestinal tract yielded negative results. During the past six months the patient had been fairly comfortable on a low residue diet supplemented with liquid petrolatum and fluid extract of cascara sagrada daily.

Mr C., a janitor, aged 33, never suffered from constipation until the past six months. During this period, at irregular intervals his bowels became constive and he then suffered from sharp pain in the left flank. The pain was probably due to a renal calculus in the left kidney pelvis which has subsequently been removed, with complete relief of the pain.

Mr H., aged 35, unemployed, had suffered from chronic constipation since an appendectomy in 1926. It was impossible to estimate the degree of constipation, for the patient had taken cathartics almost daily over a period of five years. His stools had been small, hard, often coated with mucus, and painful to pass. At the beginning of this study the patient complained of a host of symptoms: gas and belching pain in both lower quadrants, pain during defecation, a feeling as if his intestines were "raw," and nervousness and palpitation. Roentgenograms revealed some redundancy and spasticity of the colon. Skin tests with more than 200 common allergens revealed a slightly positive reaction only to beans, beets and broccoli.

It is not our purpose to discuss the clinical aspects or the classification of cases of constipation. From the brief abstracts given it will be seen that, although the subjects were nearly all young men, several different types of constipation are represented. One would suspect that in Mr M. the constipation was due to sedentary habits and a low roughage diet. Mr H.'s case is a fairly typical example of the "irritable colon," a state midway between the states of spastic constipation and mucous colitis. Mr C.'s case would perhaps be classified by some as an instance of "reflex constipation." The remaining three patients were troubled with simple constipation although Mr E. suffered from more than the usual amount of gastric symptoms of reflex origin.

Plan—The patients subsisted on carefully selected and controlled basal diets throughout the entire period.

of the test namely, from fifty-seven to sixty-nine days, or approximately from eight to ten weeks. At intervals the basal diet was supplemented with the product under investigation. The plan of experimentation is summarized in table 1. A study of this table will reveal that in periods 1, 4 and 6 the basal diet alone was

TABLE 1—Plan of Experimentation *

Period	Description of Experimental Period
1	Basal diet only. Fiber intake ranged from 30 to 38 mg per kilogram of body weight daily. Pronounced constipation is characteristic of this level of fiber intake in healthy men.
2	Basal diet plus an amount of commercial bran that would make the fiber intake approximate 50 mg per kilogram of body weight per day. In normal men this level of fiber intake is associated with "once a day" movement.
3	Basal diet plus an amount of commercial bran that would make the fiber intake approximate 90 mg per kilogram of body weight daily. In healthy men this level of fiber intake is associated with satisfactory laxation.
4	Intervening period of subsistence on basal diet only until constipation resulted.
5	Basal diet plus an amount of a processed † bran product that would make the fiber intake approximate 90 mg per kilogram of body weight daily.
6	Intervening period of subsistence on basal diet only until constipation resulted. Same as period 4.
7	Basal diet plus fruits and vegetables so as to give a fiber intake of approximately 90 mg per kilogram of body weight daily.
8	Same as 7 and supplemented with one-half the amount of processed bran product that was used in period 5. The fiber intakes ranged from 108 to 113 mg per kilogram of body weight daily.

* In the case of Mr. H., who presented the picture of "irritable colon" an attempt was made to subsist on the diet used in period 7, but this was unsuccessful; the patient's condition became worse, and therefore the tests with periods 7 and 8 were abandoned. Instead the patient was given the basal diet plus an amount of dried powdered agar-agar approximately equal to the amount of commercial bran used in period 3. This was not well tolerated; when one-half of this amount of agar was given, the patient's condition was interpreted as being "very satisfactory."

† By processed bran product is meant a material made from milled wheat bran mixed with other ingredients, chiefly sugar, so as to constitute a palatable food of the "bran breakfast food" type comparatively rich in crude fiber.

ingested, but only period 1 is called the basal period. There is a definite reason for this. In every case period 1 was at least six days long, and, taken with the preliminary period during which the exact amounts of the foods to be taken daily were being determined, gave a period of at least ten days (in one instance fourteen days) on the low fiber diet. We feel that this therefore constitutes a basal period in the real sense of the word. Periods 4 and 6, on the other hand, were not as long, being determined by the development of constipation and the patient's desire for some change that might improve laxation, in view of the earlier studies on healthy men we feel that in periods 4 and 6 there may have been some hang-over effect of the previous periods, and therefore we have called these periods intervening periods of subsistence on basal diet only.

Diet—All meals were eaten in the laboratory. Representative samples of the foods used were analyzed for moisture and crude fiber.³ The details of the diet were determined during a preliminary period in the same manner as that described in a previous paper.¹ As an illustration of the basal diet finally selected we present in table 2 the rations used by Mr. J. in the basal periods and in period 7, when fruits and vegetables were used as the supplements.

The factor of hydration was controlled as in the previous study on healthy men by measurement of the normal daily intake of fluid during the preliminary period, selection of a desirable daily volume of fluid intake, and adherence to this standard thereafter throughout the experiment. In this way each person conformed to his own desired standard with respect to fluid intake.

³ Official methods of the Association of Official Agricultural Chemists, 1925, were used.

Other Data—The men were asked to defecate, as far as possible, only when there was the definite urge to do so. They were provided with cardboard cartons so that any stools passed at home could be saved and brought to the laboratory. All dejecta were weighed as far as possible immediately on passage. When passage took place at home or elsewhere the tare weight of the cartons, which was known, was considered in arriving at the true weight of the stool. The specimens were dried in a current of warm air, the samples belonging to a given experimental period collected, mixed, ground and analyzed for moisture and crude fiber. Wood charcoal (norite) was used to differentiate the stools of different periods. Each patient recorded the time that each stool was passed and his subjective impressions with respect to ease of passage and similar observations.

RESULTS

Subjective Impressions—Each of the individuals interpreted his laxative condition while on the basal diet alone—periods 1, 4 and 6 (table 1)—as one of pronounced constipation. This agrees with the results obtained with healthy men in the earlier studies, in which it was observed that a daily fiber intake of from 30 to 40 mg per kilogram of body weight was associated with marked constipation. The degree of discomfort experienced by the men in the present investigation seemed to vary somewhat. In period 2, when commercial bran was added to the diet in amounts sufficient to bring the daily level of fiber intake up to about 50 mg per kilogram of body weight, all the men except Mr. H. reported improvement but with their laxative condition being still far from ideal. In period 3, in which the basal diet was supplemented with still more commercial bran so as to make the level of fiber intake approximate 90 mg per kilogram daily, all the men again, with the exception of Mr. H., experienced a distinct improvement in laxative condition and stated

TABLE 2—Diets Used by Mr. J. (Body Weight, 83.2 Kg.)

Basal Periods		Period 7

		Raisins	50 Gm
		Tuna fish	50 Gm
Fiber content 2.78 Gm, or 33 mg per kilogram		Fiber content, 7.32 Gm, or 88 mg per kilogram	

In period 2, to get a total fiber intake of about 50 mg per kilogram per day, 18 Gm (3/4 ounce) of commercial bran was taken as a supplement at the noon meal.

In period 3, to get about 90 mg per kilogram per day of fiber 44 Gm (1 1/2 ounces) of commercial bran was taken as a supplement, one-half at the noon lunch and the remainder at the evening meal.

In periods 5 and 8 55 Gm (2 ounces) and 28 Gm (1 ounce), respectively, of a processed bran product was taken as a supplement daily at the evening meal.

that conditions were satisfactory, judging from subjective impressions. The exceptional individual, Mr. H., it should be remarked, presented the picture of "irritable colon"; he was more comfortable when receiving the basal diet alone than when receiving any supplements designed to increase the fiber content.

After an intervening period of subsistence on the basal diet alone until constipation resulted (period 4), the ration was supplemented with a processed bran product in amounts sufficient to bring the total daily fiber intake up to about the 90 mg per kilogram level. With the exception of Mr H, all the men reported their laxative conditions as being satisfactory, but with a slight difference in favor of commercial bran. On the other hand, they also reported that the processed bran was much easier to eat in appreciable quantity, and for that reason greatly to be preferred.

After another intervening period on the basal diet alone, a trial was made of a ration again containing about 90 mg of fiber per kilogram daily but with almost all the fiber furnished by fruits and vegetables. An example of the type of ration used here is given in table 2.

It is important to note that Mr H, with the "irritable colon," could not tolerate this diet and therefore had to return to subsistence on the basal diet alone, as explained in the footnote in table 1. Of the remaining five persons, two—Mr F and Mr C—considered that their laxative condition was satisfactory while on the regimen of fruits and vegetables. The other three men did not regard their condition as satisfactory and desired to supplement this diet with the processed bran product and therefore took daily one half of the quantity that had been taken during period 5 (table 1). As a result of this addition, the laxative conditions of these men improved and were interpreted subjectively as "very satisfactory."

Interval Between Defecations—In our previous studies it was pointed out that in healthy men the average duration of the interval between defecations is a rough measure of the extent to which laxation is taking place. It becomes of interest, therefore, to inquire as to the duration of this interval in the patients here studied. In table 3 are given the averages of these intervals in hours yielded by the data of the present investigation. In the last column of the table are presented the averages of the data from comparable earlier experiments, which were performed on healthy men. It should be stated that the data from the previous investigation on healthy men showed much less variation than the data obtained from the present study made on individuals suffering from constipation.

It will be noticed in table 3 that in the case of Mr J the intervals were not far from twenty-four hours, representing a laxation rate of once a day, except in period 6 when there was marked constipation, indicated by the average interval of fifty-four hours, and in period 8 when the highest level of fiber intake was tried and the interval thereby reduced to sixteen hours. Mr J had long been troubled with constipation and had endeavored to meet this condition by regulating his diet. We are of the opinion that he may have conditioned himself more or less to a once-a-day regimen, and therefore over much of the earlier part of the present study was making an effort to secure a bowel movement every day. This supposition is supported by the fact that he exhibited this rate of laxation even when the average weight of the fresh stool was as low as 38 Gm (table 4). It is possible that the experimental regimen and our emphasis on the importance of defecating only when there was a definite urge to do so was to some extent responsible for the long interval of fifty-four hours obtained in period 6.

The results with Mr M are interesting because of the extremely long interval of 77 hours recorded for

period 1, associated with the very low laxation rate¹ of 0.3, the lowest encountered in these studies. The effect of raising the level of daily fiber intake is evident as one examines the figures for Mr M for all periods. It will be noticed that the average duration of the interval was finally reduced to sixteen hours by the ingestion of as much as 113 mg of fiber per kilogram daily.

In the case of Mr E, the average interval between movements was quite definitely related inversely to the level of fiber intake. There is a definite suggestion that the ingested fiber of fruits and vegetables, period 7, did not function very well as a roughage, when the processed bran product was taken, period 8, the result was about the same as that obtained previously in period 5, when this bran product alone was tested.

In the case of Mr F the results were about the same as those obtained with Mr E except with respect to the regimen of fruits and vegetables. Mr F regarded his laxative condition during period 7 as quite satisfactory, although the average interval was twenty-four hours.

TABLE 3—Average Duration in Hours of the Interval Between Defecations

7 Fruit and vegetable diet the fiber intake about 90 mg per Kg per day	21	31	40	24	9		19
7 Same as 7 and supplemented with the processed bran product fiber intake 108-113 mg per Kg per day	16	10	24				

* An abbreviated form of the periods is given in this table and in tables 4 and 5. A more detailed description is given in table 1.
† Average for healthy men at this level of fiber intake.

Mr C's was classified as a possible "borderline irritable colon" case, because of the great number of stools passed, revealed by the data contained in table 3, in which the average interval was fairly constant and hardly indicative of constipation. Nevertheless, this patient experienced discomfort during the basal periods and considered his condition much better when the diet was supplemented with the commercial bran, the processed bran product, or the fruits and vegetables. It is quite possible that the patient was more sensitive than are healthy men to the presence of material in the large intestine and therefore received the urge to defecate oftener. The improvement, which, he believed, was associated with increased level of fiber intake, may possibly have been due to the slightly greater average weight of stool passed at each movement, the passage of the larger stool may have given a greater sense of complete emptying, which seems to be an important subjective factor, judging from the earlier observations on healthy men.

From this brief summary of the data in table 3 it appears that in three of the cases (M, E and F) the relation between the duration of the interval between defecations and the level of fiber intake is the same

as that occurring in healthy men, but the average duration in hours tends to be slightly longer in the case of these patients. In the three remaining patients, this relation is not exemplified, but special factors appear to be playing a rôle.

Amount of Intestinal Contents Eliminated—In the earlier studies performed on healthy men it was noticed that an increase in laxation is accompanied by the

appears to have had a remarkable capacity for retention of material in the lower bowel. In periods 2, 3 and 7, the average weights of his stools were 246, 271 and 262 Gm, respectively, weights considerably greater than those yielded by the healthy men in the previous studies, the greatest of which was only 158 Gm. Other high figures that might be cited are those for Mr. J in period 6, and Mr. E for periods 3, 5 and 7. These results support the observations of Hines, Lueth and Ivy and are doubtless to be attributed to the diminished sensitivity of the lower bowel to the presence of fecal material which some cases of constipation show.

It will be noticed that these unusually high average weights of stools were associated with low rates of laxation, although the amounts of material eliminated daily were comparable to those observed in the previous studies and were indicative of definite change in laxation. This suggests that in the interpretation of the data of the rate of laxation it is important to consider also the average weights of the dejecta as well as the amounts eliminated daily.

In conclusion it appears that, with respect to the relation of the level of fiber intake to the amount of intestinal contents eliminated, the results yielded by these patients are not essentially different from those obtained earlier from healthy men. There is evidence indicating that in these cases of constipation there is a decreased sensitivity of the lower bowel to the presence of fecal material. In these instances, nevertheless, commercial bran and the processed bran product were demonstrated to have definite laxative power.

TABLE 5—Percentage of Ingested Crude Fiber that Disappears During Passage Through the Alimentary Tract

Period	Person						Aver age	Aver age†

* Average of data from healthy men.
† Data for Mr. H were omitted in calculating this average.

Fiber Intake and Laxation—In the earlier studies on healthy men it was found that there exists a definite quantitative relationship between the amounts of crude fiber ingested daily and the laxative performance. On the basis of these results it was suggested that there exists what might be called a "physiologic fiber or roughage minimum." It becomes of interest, therefore, to see to what extent the data yielded by the present study confirm or disagree with this suggestion.

In table 5 are given for each person the data indicating to what extent the ingested fiber disappeared during

* The first figure given in each group indicates the average weight of material in grams eliminated per day, the second gives the average weight in grams eliminated at each defecation, the third indicates the rate of laxation or number of movements per day. For example, in period 1, J eliminated 49 Gm of stool per day, an average of 38 Gm at each movement, and showed a laxation rate of 1.17 movements per day.
† Average of previous study on healthy men.

elimination of greater amounts of intestinal material, and from this work there came the suggestion that the urge to defecate may be due to a certain extent to the existence of what might be spoken of as a "threshold mass" in the lower bowel. In view of the observations of Hines, Lueth and Ivy* indicating a lowered sensitivity of the rectum of patients suffering from chronic constipation, one might expect a failure of the "threshold mass" idea to apply to the patients here studied. In table 4 are given the average weights of dejecta passed daily and for each movement, the rates of laxation, the averages for the different experimental periods, and comparable data yielded by the earlier studies.

If one compares the levels of fiber intake (first column of table 4) with the average weights of the amount of material eliminated daily (next to last column, table 4), a definite parallelism will be noted. This agrees with the results obtained in the earlier study on healthy men and confirms the view that the amount of intestinal excreta passed daily can serve as a criterion of the prevailing state of laxation.

When the data in table 4 for the amount of material eliminated at each movement are examined, some interesting variations are noticed. For example, Mr. M

4 Hines, L. E., Lueth, H. C., and Ivy, A. C. Motility of the Rectum in Normal and Constipated Subjects. Arch. Int. Med. 44: 147 (July) 1929.

its passage through the alimentary tract. Comparison of these figures with those for the fiber intake (corresponding periods, column 1) indicates very clearly that a much smaller fraction of the supplementary fiber—that of commercial bran, the processed bran product and the fruits and vegetables—disappeared during alimentary passage than was the case with the fiber of the basal diet. In the last column of table 5 are given some comparable data taken from the previous studies on healthy men. Comparison of these figures with those yielded by the present investigation (next to the last column) indicates very definitely that the fiber of the basal diet suffered a much greater decomposition in the case of the patients of the present study than was the case with the healthy men studied previously. Whatever the cause of this may be, possibly a particular bacterial flora, it seems reasonable to attribute the pronounced tendency to constipation which these patients exhibited to this fact that too small a fraction of the fiber ingested as part of the customary diet remains intact in the alimentary tract to function satisfactorily in a mechanical way as roughage to stimulate the normal eliminatory process.

In view of these results, the stability of the fiber, ingested as part of the commercial bran, the processed bran product and the fruits and vegetables under the same conditions, becomes important to determine, for on the results of such determinations depend to a very high degree the values of these substances as laxatives for such cases. In making such determinations it is necessary to assume that, during the period when the test supplement is being ingested, the same fraction of fiber of the basal diet remains intact after alimentary passage as was the case in the previous period when only the basal diet was being consumed. As the time during which the fiber remains in the intestinal canal is undoubtedly a factor determining the extent to which decomposition takes place, and as the use of any effective supplement shortens the time somewhat, this assumption cannot be entirely accurate. In the absence of any alternative plan by which to make the desired comparison this method, even in the face of the uncertain assumptions which it involves, has been followed.

An illustrative calculation should suffice to make clear the method used. In period 1, Mr. J. ingested a total of 18.54 Gm. of crude fiber, and eliminated by way of the stools only 1.54 Gm., or 8.3 per cent. In period 2 he ingested a total of 64.96 Gm. of fiber, 38.92 Gm. of which came from the basal diet and 25.9 Gm. from the commercial bran supplement. The total output during this period was 39.4 per cent, or 25.57 Gm. If one assumes that 8.3 per cent of the fiber of the basal diet was eliminated in this period as was the case during the first period then in period 2 there would be 3.23 Gm. of fecal fiber contributed by the basal diet. On subtracting this amount from the total output for the period one obtains 22.34 Gm. of fiber contributed by the supplement which in this case was commercial bran, this constitutes 86 per cent of the bran fiber that was ingested. Therefore one may say that only 8.3 per cent of the fiber of the basal diet was eliminated in contrast to 86 per cent of the fiber of the commercial bran. In all of the calculations the results of which are summarized in table 6 the data obtained in the basal period 1 were taken as properly representing the influence of the basal diet alone. For reasons already given, we do not think that in periods 4 and 6 the maximum effect of subsistence on the basal diet alone was obtained.

The results of the calculations made to determine the relative stability in the alimentary tract of the various sources of fiber used in this investigation are summarized in table 6.

In column 3 of table 6 it will be noticed that in basal period 1 the amount of ingested fiber recovered in the stools was quite low, ranging from 8 to 21 per cent. These figures should be compared with those for period 2 in column 4, which represent the percentage recoveries of the commercial bran fiber which supplemented the basal diet. In period 3, during which the amount of commercial bran ingested was such as to

make the total fiber intake approximate 90 mg per kilogram daily, in contrast to 50 mg during period 2, it will be noticed that, with the exception of Mr. H, the patient with the "irritable colon," about 94 per cent of the fiber of the ingested bran was recovered in the stools. The figures for period 5, during which the processed bran product was tested at the 90 mg level of fiber intake, are somewhat variable and indicate somewhat smaller recoveries of ingested supplementary fiber. The results obtained with the diet in which fruits and vegetables furnished the supplementary fiber (period 7) are worthy of consideration. The average is 20 per cent, which is only slightly greater than the average for basal period 1 and identical with that for intervening period 6. From this it appears that in these

patients the fiber of the fruits and vegetables used as supplements suffered about the same degree of decomposition during alimentary passage as that of the foods used in the basal ration. This emphasizes further the fact that the fiber contained in the foods ordinarily used was more readily broken down during passage through the alimentary tracts of these patients than is true of healthy men, and on this fact one may rest an explanation of the great tendency to constipation which characterized these individuals. Since the fiber of commercial bran and of the processed bran product resisted this decomposition to a very considerable degree, and since the use of the materials was not attended with undesirable symptoms of any kind, these products may be considered to have special value as sources of roughage for such patients.

It will be noticed in table 6, by a comparison of periods 3 and 5, column 4, that the fiber of the commercial bran was somewhat more resistant to alimentary decomposition than that of the processed bran product. This finding agrees with the others pertaining to subjective impressions, amounts of material eliminated and rates of laxation. All of the men reported, however, that it was not easy to ingest appreciable quantities of commercial bran, the processed bran product, on the other hand, presented no such difficulty and therefore was greatly to be preferred as the source of supplementary fiber. It is suggested that perhaps the slight difference here noted may be related to the fact that fiber of the processed product is in a more finely divided state than that of the commercial bran and that, therefore, when the fiber of the processed product is suspended in the semiliquid chyme of the intestinal contents, more surface is available to the action of bacteria, or special ferments, with a resultant greater decomposition.

The relation between the level of fiber intake and laxation is shown. The curves indicate that for a given fiber intake laxation was poorer in the patients than was the case in the healthy men.

It will be noticed that in period 8 the processed product was tried as a supplement to the diet of fruits and vegetables and proved effective in promoting satisfactory laxation. Evidently, then, the fiber of the more palatable, easily ingested processed bran product here studied was sufficiently stable in the alimentary tract to give this material definite value as a supplementary source of fiber taken to promote laxation.

In table 7 are presented data from the previous investigation, which are believed to be fairly comparable to those obtained in the present study. The data from Mr C and Mr H were not considered here because both of these men gave some evidences indicative of so-called irritable colon, the remaining four patients, as

described elsewhere, suffered from simple constipation only and therefore may properly be compared as a group with the healthy men studied previously.

The data contained in table 7 have been plotted on coordinate paper with the result presented in the accompanying chart. The plot shows that in the two groups of men the same general relation exists between the level of daily fiber intake per kilogram of body weight and the laxative performance as indicated by the average interval between defecations, however, in the case of the patients, as indicated by the higher position of the curve, laxation was poorer than in the case of the healthy men, thus suggesting the existence of definitely

TABLE 7—Comparison of the "Physiological Fiber Minimum" of Healthy Men and Patients Exhibiting Simple Constipation

Fiber Intake per Day, Mg per Kg	Average Duration of Interval Between Defecations	
	Healthy Men, Hours*	Patients, Hours†
21 to 42 (average 31)	30	41
51 to 65 (average 58)	24	32
82 to 100 (average 90)	19	22
103 to 112 (average 107)	17	19

* Average of results from previous studies.
† Patients C and H were not considered because they presented some evidence of "irritable colon."

higher fiber or roughage minima characteristic of the patients. The study of the fiber intake and output (table 5) indicates that the chief reason for this higher "fiber minimum" in the case of these patients lies in the greater destruction of ingested food fiber during passage through the gastro-intestinal tracts of these individuals. For example, in table 5, 85 per cent of the ingested fiber of the basal diet disappeared during alimentary passage in contrast to 60 per cent for the healthy men, as shown by a comparison of the figures in the last two columns of table 5.

It will be noticed in the chart that at the highest levels of fiber intake studied, the two groups tend to exhibit almost the same degree of laxation. In this connection it should be remembered that at these high levels most of the ingested fiber was contributed either by commercial bran or by a processed bran product and therefore was present in a form that resisted decomposition in the alimentary tract to a very high degree (table 6). Under these conditions, therefore, the two groups might be expected to show about the same degree of laxation. In general, it appears reasonable to conclude that these data yielded by the patients suffering from simple constipation confirm the hypothesis that there is a physiologic fiber or roughage minimum intake which is necessary in order to promote satisfactory laxation.

TESTS WITH AGAR-AGAR IN A CASE OF "IRRITABLE COLON"

Mr H presented the general picture of so-called irritable colon. In all the experiments with the basal diet, commercial bran, processed bran product, and fruits and vegetables, the patient was most comfortable when subsisting on the basal diet alone (periods 1, 4 and 6), in spite of the fact that his laxative condition during these basal periods was one of definite constipation. It should be emphasized here that the bran products were not unique with respect to their undesirability in this case, a diet having the same fiber content but with the fiber furnished almost entirely by

fruits and vegetables was equally unsatisfactory. Evidently, then, fiber itself, regardless of the source, is contraindicated in such a case.

Alvarez believes that agar-agar is the best source of roughage to use clinically. Many clinicians have gained the impression that the fibrous roughage in certain foods is present in large discrete particles and that the undesirability of these foods for certain clinical cases is related to this. The expressions "bland diet" and "smooth diet" are generally understood to mean a diet free from "coarse" fiber in contrast to diets into which these "coarse" foods enter. Celery, fresh sweet-corn and other vegetables are instances of some commonly recognized "coarse" foods. On the other hand, agar-agar forms a gel when mixed with water and therefore presumably exerts its function as an indigestible roughage in the form of a soft jelly-like mass. In view of these considerations, it seemed desirable to test the efficacy of agar-agar as a laxative on Mr H.

At first the agar was added to the basal diet in such an amount as to make the daily roughage intake equal to about 90 mg per kilogram of body weight, the patient could not tolerate such a large intake. The dose of agar was then reduced so as to make the total roughage intake equal to about 50 mg per kilogram daily. Under these conditions Mr H was more comfortable than he had been before. From these admittedly few observations, made, however, under carefully controlled dietary conditions, it is clear that there may be a real basis for the contention of Alvarez that agar-agar has definite clinical value as a laxative. It is also clear that the dosage of even this product is important, too much of it being as undesirable as too little. Further work should be done on this problem.

COMMENT

At the beginning of this investigation, one of the authors (A. J. S.) was quite skeptical as to the value of bran in the treatment of constipation. He felt that the work on healthy individuals¹ was of interest but was probably not applicable to patients suffering from constipation. He had seen many patients who said that they had "tried bran" without relief of their constipation. He had seen some patients whose symptoms were quite definitely aggravated by the use of bran and other forms of roughage, and he was acquainted with the literature reporting cases of intestinal obstruction due presumably to bran. It is quite likely that because of unsatisfactory results in some cases he had swung to the extreme view held by many physicians at the present time that bran is contraindicated in all cases of constipation.

Observations on these six subjects suffering from constipation indicate that in certain cases bran will induce quite satisfactory laxation. At this point we must again emphasize the fact that all of our subjects were free from any organic disease of the gastrointestinal tract, with the possible exception of Mr H, whose case would be diagnosed as "irritable colon." It is interesting that he was the only one whose symptoms were aggravated by bran, whether in the crude form or in a milled product or by the fruits and vegetables tried, he was most comfortable when subsisting on the basal low-roughage diet. We agree with Alvarez that a bowel which is ulcerated, narrowed or highly irritable should not be subjected to the stimulus and added burden of highly indigestible material. On the other hand only a small percentage of individuals complaining of constipation suffer from organic diseases thus

falling outside the major group to which the "physiologic roughage minimum" principle applies. Most individuals treat themselves for costive tendencies, perhaps employing drastic measures for extended periods, the physician being consulted only when other symptoms appear or when complications ensue. At this stage, roughage may do more harm than good.

Our investigations indicate that bran was a satisfactory source of roughage in five out of the six cases of constipation studied. Four out of the five patients were definitely convinced of the value of bran in their cases as a result of their experience in this study and have continued its use for the past five months with excellent results. The fifth patient could not carry bran on a camping trip but intends to use it during the coming year. Mr H, the sixth patient, is now quite comfortable on a bland diet plus agar-agar.

It has been argued that it is absurd to prescribe bran or bran products as sources of roughage when one merely needs to have the patient eat more green vegetables and fruit to supply the needed bulk. In two of our patients, Mr F and Mr C, a diet high in vegetable roughage was just as satisfactory as the use of bran. On the other hand, three of the patients were not comfortable until they had added processed bran to the high fruit and vegetable diet. The study of the fiber content of the stools indicates that most of the vegetable fiber was being destroyed in the intestine. This not only confirms earlier studies reviewed by Schmidt and Strasburger,⁵ showing that there is a variable utilization of the cellulose contained in different vegetables, but also emphasizes that the utilization of the fiber of the same vegetable may vary markedly in different individuals. Mr M, stated that he did not like vegetables and rarely ate them. He definitely preferred to take his roughage in the form of 2 ounces (60 Gm) of the processed bran product rather than as 150 Gm of peas, 120 Gm of peaches, or 50 Gm of raisins (table 2), for example.

SUMMARY AND CONCLUSIONS

The laxative values of commercial wheat bran, a processed bran product, and a mixed diet of fruits and vegetables were studied in a group of six male patients exhibiting varying degrees of constipation. The patients subsisted on carefully selected diets the fiber contents of which were determined by chemical analysis. The several criteria of laxative action developed in studies on healthy men were used in the present investigation.

In all but one instance, the commercial bran and the processed bran product, when fed in such amounts as to bring the daily fiber intake up to 90 mg per kilogram of body weight, were very efficacious in correcting the constipation, in contrast to fruits and vegetables, which proved to be satisfactory in only two cases. The commercial bran proved to be slightly superior to the processed bran product but was much less palatable and proved difficult to ingest in reasonable quantity, no difficulty whatever was experienced in eating the processed product. It is suggested that the smaller size of the fiber particle in the processed bran product is a factor tending to decrease slightly its laxative value. In the three cases in which satisfactory laxation was not secured when the patient was subsisting on the diet of fruits and vegetables, addition of the processed bran product resulted in the desired improvement.

⁵ Schmidt, E. A. and Strasburger, Julius. *Die Fazes des Menschen*, ed. 3. Berlin: August Hirschwald, 1910. pp. 211-216.

In each of the five cases that presented constipation without any other symptoms, it was observed that the fraction of the fiber of the basal diet and of the fruits and vegetables that remained intact after passage through the alimentary tract was much less than was the case with the healthy men studied in the earlier investigations. It is suggested that the tendency to constipation which these patients exhibited was due to this fact. A diet of common foods that will suffice to promote satisfactory laxation in healthy persons evidently will do so in some of these patients but not in all, and, therefore, the latter require some form of roughage that will resist all decomposition. Both commercial wheat bran and the processed bran product tested in this study were found to be satisfactory sources of fibrous roughage for these patients.

In the one case presenting the picture of so-called irritable colon, fibrous roughage in any form, whether commercial wheat bran, a processed bran product, or fruits and vegetables, was contraindicated. Agar-agar, on the other hand, when fed so as to give a roughage intake of about 50 mg per kilogram daily, gave very satisfactory results, when fed at a 90 mg level of daily intake, it could not be tolerated. This observation in a single case suggests the advisability of further study of the clinical value of agar as a source of roughage.

DOES THE GUINEA-WORM OCCUR IN NORTH AMERICA?

B. G. CHITWOOD, PH.D.

WASHINGTON, D. C.

The guinea-worm, *Dracunculus medinensis*, has been reported from man in North America in a total of ten published cases. In four of the cases, *D. medinensis* was collected from persons who had been abroad in countries in which guinea-worm is known to be endemic and who either certainly or possibly became infested while abroad. In six other cases the evidence published in connection with the cases indicates that the supposed *D. medinensis* was actually something else. The net result of a consideration of the published literature is a total lack of human cases that can be accepted as originating in the United States.

The four cases of *D. medinensis* infestation reported from the United States with evidence that the infestation was or might have been acquired abroad, are as follows:

Severance¹ reported a case in a white sailor who had been in Mogador, Morocco, six years previously. The worm made its appearance while the patient was en route from New Orleans to New York. The time required for the worms to mature is generally stated to be from nine to fourteen months, but sometimes a considerably longer period elapses before the worm makes its presence known by appearing on the surface of the body. The origin of this case must be considered problematic.

Burst² added two cases in which the patients had recently returned from East India to South Carolina. The first case was that of an Englishman, aged 34, who

had shipped six months previously from a port in India to Liverpool, and a few days after his arrival in England had shipped to Charleston, S. C. While this man was en route between Liverpool and Charleston, the worm made its appearance between the heel and the inner malleolus and was extracted from the lesion, the worm was 16 inches (40 cm) long. In the second case, a Danish seaman, aged 28, had also recently returned from India. In this case the worm made its appearance near the inner malleolus and was extracted, it was 18 inches (45 cm) long. These are evidently valid cases of *D. medinensis*, with infestation acquired abroad.

Francis³ added the fourth case, that of a male black native of the Gold Coast, Upper Guinea, in whom the worms made their appearance while the patient was en route to the Buffalo Exposition for exhibition purposes. The patient had a previous history of having had three worms appear on the feet. While he was in the United States, five worms, from 12 to 26 inches (30 to 65 cm) long, appeared on the feet and ankles. This also is a valid case, with infestation acquired abroad.

The six cases in which the thing reported as *D. medinensis* appears to have been something else are as follows:

Barkan⁴ described a case of a man, aged 30, a native of Adelaide, Australia, who entered a hospital shortly after arriving in California. The patient stated that he had had trouble with his eyes for years. The left eye was found to contain a stationary foreign body which was removed surgically, together with that part of the iris to which it was attached. Subsequent examination of the specimen by Professor Knapp corroborated the physician's diagnosis of *Filaria medinensis*. It now appears probable that this case is a record of the occurrence of *Loa loa*, a more common parasite of the eye, which in the past has at times been confused with *D. medinensis*, the parasite probably being of foreign origin in this case.

A case was reported by Jarvis⁵ in which a small, bristle-like structure, 1½ inches long, was obtained from under the skin of the foot of a patient at Fortress Monroe, Va. The author stated that the worm appeared similar to a "hog bristle." This is probably a case of spurious parasitism.

Walker⁶ reported a case, which he attributed to *D. medinensis*, in a 3 months old child in Arlona (?), Putnam County, Ga. He described the case as follows:

The only child was apparently healthy until about three months after birth, when a small red speck was noticed on the gluteal muscles, at or near the rim of the pelvis, which gradually enlarged to the size of a pea, of oval shape, and in about two weeks after its discovery it began to elongate and to descend the thigh, making perhaps the distance of two lines a day. The cordlike object was well defined under the skin. The worm, as I shall call it, went on in a zigzag course downwards, nearly passing around the limb. The anterior part, for perhaps an inch, was of a bright scarlet color and grew paler upwards. The head had reached the lower half of the leg, I cut across it in several places and one cut was made half an inch from the head, and from this cut there oozed out a few drops of a light, thin yellowish fluid.

² Burst, I. B. Cases of *Filaria Medinensis*, Guinea Worm or *Dracunculus*, Fr. South Carolina M. A., sixth meeting 1874 pp. 104-108.

The anterior fragment of the worm progressed farther and was repeatedly cut. It remained four months and disappeared. The parents were of filthy habits. This appears to be a case of creeping eruption due to *Ancylostoma braziliense*, a condition known to occur in Georgia.

A similar case was reported by Van Harlingen⁷ in which a man, aged 47, who had never lived outside of Philadelphia, was employed at the time in the custom house examining invoices from foreign countries, he was never in contact with goods imported. According to this report

Some time in September last (four months previously) the patient first noticed a small red papule under the skin of the back of the hand. The lesion gave rise to considerable pruritus but no pain. It soon assumed an elongate form and began to elongate at one end, taking on a serpentine form and pushing along under the skin throwing the epidermis up into a ridge, and showing beneath it like a sinuous red cord.

The worm, for such it appeared to be, progressed slowly over the back of the hand between the index and middle finger and down across the palm. It was five to six inches in length and about an eighth of an inch in breadth. The head of the parasite appeared to be near the radial side and just turning from the palm to the back of the hand. Concluding from the appearance that I had to deal with *Filaria medinensis*, I cut down upon the parasite, hoping to demonstrate its presence and perhaps to remove it. By traction. For some reason or other, probably awkwardness, I failed to find the parasite on two successive occasions.

The sinuous cord finally disappeared. This might have been a case of creeping eruption but it cannot be accepted as a case of *D. medinensis*. The cases reported by Walker and Van Harlingen showed lesions which correspond closely to the lesions reported by Kirby-Smith, Dove and White⁸ and White and Dove⁹ and others for creeping eruption caused by larvae of the hookworm *Ancylostoma braziliense*.

Leidy¹⁰ described a nematode in the collection of the Philadelphia Academy of Sciences labeled "obtained from the mouth of a child." The specimen was $5\frac{7}{8}$ inches long by $\frac{1}{250}$ inch wide at the mouth and $\frac{1}{40}$ inch wide toward the posterior extremity. He named this worm *Filaria hominis-oris* and suggested at the time that it might be the male of *D. medinensis*, his opinion being based on the statement that this parasite was often introduced into this country by the importation of Negro slaves. Leidy¹¹ later confirmed his previous opinion that *Filaria hominis-oris* was *D. medinensis*, after examining a specimen of *D. medinensis* from Africa. In spite of Leidy's opinion, it appears possible that this worm was a specimen of *Gongylonema*, perhaps *G. pulchrum*, as *Gongylonema* is reported from the lips and inner surface of the cheek in man in the United States in several cases, and the brief description of the worm does not preclude this possibility.

Although there appear to be no valid records of *D. medinensis* in man in cases originating in the United States there is nevertheless, evidence that this worm is enzootic in the United States. The guinea-worm is known to occur in various wild and domesticated mammals of the Old World, including the wolf, hunting

leopard, pole cat, dog and horse, and appears to be present in wild carnivores in the United States and Canada. Benbrook¹² has recently reported *D. medinensis* from the fox, and I have studied specimens of *Dracunculus* collected from the following hosts: the silver fox, *Vulpes fulva*, from Iowa (a part of the collection which formed the basis for Benbrook's report), the raccoon (*Procyon lotor*), from Ontario and New York, and the mink, *Putorius vison*, from Nebraska. These specimens appear to be morphologically identical with the guinea-worm of the Old World, *D. medinensis*. The specimens that I have studied vary in size from 16 to 36 cm long by 1.4 to 1.8 mm wide. Records of specimens from India and Africa vary from 16 cm to 4 meters in length, from 45 to 70 cm appears to be the usual length of specimens collected from man and large mammals, but there are numerous records of specimens from 25 to 30 cm long, such specimens being more often found in the small mammals, in human infants or in abnormal locations such as the tongue, finger and penis. One case comparable to mine was reported by Cinotti¹³ from a dog in Egypt, the worm being 36 cm long.

Examination of the North American specimens shows that the head bears the cuticular "helmet" and the mediodorsal and medioventral cuticular projections which are characteristic of the guinea-worm. The tail is conical and curved ventrally, and the larvae agree in every respect with *D. medinensis*. Morphologically on comparison with material from India, the specimens collected from the fox, raccoon and mink appear to be *Dracunculus medinensis*. Moreover, the parasite does not appear to be a recent introduction, since Leidy¹⁴ described a nematode, *Filaria insignis*, from the raccoon, *Procyon lotor*, which appears from his description to be *D. medinensis*, and since the wide distribution of the species, as indicated by the sources of my material, points to the likelihood that the parasite must have been here a long time in order to range from New York to Nebraska and from Iowa to Ontario.

It would appear that our native wild mammals harbor this highly important parasite, *Dracunculus medinensis*, which is most widely known from man in the Old World. It may be that this is a physiologic strain or variety which is not adapted to man or that living conditions here account for the fact that up to the present time it has not appeared in naturally acquired infestations as a parasite of man on this continent. In view of the fact that in the Old World the worm parasitizes both man and lower mammals, the presumption is that it is capable of parasitizing both man and animals in North America and that the freedom of man from infestation in North America is correlated with a difference in habits. In the Old World the prolific sources of infestation appear to be the shallow open wells and ponds in which persons wade and bathe and from which they drink. The worm is said to occur in the lower limbs of 85 per cent of the infested persons, and when such persons wade or bathe the worm discharges myriads of larvae into the water. These larvae develop in small crustaceans, species of *Cyclops*, and when water containing *Cyclops* with infective larvae is drunk by man or animals, the worms develop to maturity in the new host. In the United States and

Canada it is not customary for man to drink from the pools in which he bathes or to bathe in the pools from which he drinks. Our water supplies in general are of a sort which is free from contamination of the kind necessary for the propagation of this parasite in man, and it would be only under quite unusual conditions that human infestation with this worm would occur in the United States or Canada. Nevertheless, the presence in these countries of a worm morphologically identical with *D. medinensis* warrants the consideration of physicians in these countries.

SUMMARY

Of ten cases of *Dracunculus medinensis* reported from man in the United States, four are certainly or possibly of foreign origin and six are not cases of *D. medinensis* but apparently are cases of *Loa loa* of foreign origin, of spurious parasitism, and, in one case, possibly *Gongylonema*.

Dracunculus occurring in the fox, raccoon and mink, in Nebraska, Iowa, New York, Pennsylvania (?) and Ontario, is morphologically identical with *D. medinensis*, and probably is *D. medinensis*.

TOTAL GASTRECTOMY FOR CARCINOMA

PHYSIOLOGIC AND CHEMICAL STUDIES DURING A
PERIOD OF TWO YEARS FOLLOWING THE
OPERATION

WALTMAN WALTERS, M.D.
ROCHESTER, MINN.

Before considering the case which is the main interest of this paper, I wish to review certain aspects of another case.

REVIEW OF PREVIOUS CASE

I first performed total gastrectomy for carcinoma of the stomach in August, 1929. The patient's return to the clinic four months following the total gastrectomy, that is, in January, 1930, gave me an opportunity to make physiologic and chemical studies, which were reported in detail in 1930.¹ A summary of, and comment based on, those studies is as follows:

"In view of the absence of secondary anemia in experimental animals after total gastrectomy, in which more than four years has elapsed since the operation, the question naturally arises whether the cause of secondary anemia in human beings in whom total gastrectomy has been done is the result of local recurrence of the malignant growth or of remote metastasis. The cases reported by Brigham, Moynihan and Mayo are exceedingly interesting in this respect. In Brigham's case, in which the anastomosis was between the esophagus and the duodenum, the patient was well for two years following total gastrectomy, and the normal formula of the blood was not affected. In Moynihan's patient, who lived three years and eight months following total gastrectomy, marked anemia occurred, but evidence of recurrence of carcinoma was not found at post-mortem examination. In a case in which gastrectomy was performed successfully by W. J. Mayo, the patient lived for almost four years, but, before death, marked secondary anemia was found.

"In the case presented here, total gastrectomy was performed successfully for an extensive scirrhus carcinoma of the linitis plastica type. Studies made of the chemical changes in the blood and of the cell count over a period of four months do not reveal any appreciable change in the number of erythrocytes, in the content of the hemoglobin, in the carbon dioxide combining power, or in the concentration of blood chlorides or urea. Evidence of a definite alkaline tide has not been found. This observation is of interest, since it has been recognized that, with the secretion of gastric juice in a normal person, the urine tends to become more alkaline. The data so far, in this case, appear to indicate that the lack of a stomach and of its acid-secreting glands has a definite effect on the morning alkaline tide."

The patient was examined again, May 7, 1930, four months after these comments were made, or eight months after the total gastrectomy. Since the previous article¹ was in type at that time, results of these observations could not be included and are given here. The concentration of hemoglobin was 12 Gm. in each 100 cc. of blood, erythrocytes numbered 4,550,000 and leukocytes 10,100. The percentages of the various types of leukocytes were as follows: lymphocytes, 19.5, large monocytes, 0.5, neutrophils, 71.5, eosinophils, 3.0, and basophils, 0.5. Blood smears appeared normal except for slight deficiency of hemoglobin. Roentgen examination of the thorax and lungs gave negative results. A roentgenogram of the stomach revealed that the esophageal-jejunal anastomosis was free, without evidence of recurrence. No definite masses were felt on abdominal examination, although there were some shotty nodes in the inguinal region. On rectal examination three nodules, 1 by 1 cm. each, were felt on the rectal shelf. I was informed, June 28, 1930, that the patient had died and that the cause of death was uncertain.

Dr. Watkins and Dr. Heck, who have studied the blood of this patient, reported that prior to operation there was hypochromic secondary anemia of moderate degree. It is of interest that for a period of seven months after operation the values obtained in studies of the blood, including morphologic studies, remained practically constant. At the time of the patient's last visit the concentration of hemoglobin was relatively the same as at previous determinations, but there apparently was mild suppression of the bone marrow, as evidenced by reduced erythrocyte count, leukopenia, moderate granulopenia and moderate reduction in the number of reticulated erythrocytes. This picture might be mistaken for early pernicious anemia, but morphologic study of blood smears did not disclose the macrocytosis, poikilocytosis, and right shift of the neutrophils with the thinning and stranding of individual nuclear lobes, such as are seen in pernicious anemia. On the other hand, morphologic features of any primary blood dyscrasia were absent and the morphologic observations of the blood at this time were suggestive of a deficiency type of secondary anemia, which may be caused by inadequate diet, disturbances of metabolism which prohibit proper assimilation of essential food factors, or absence of the normal hormone and enzyme secretion, resulting in improper assimilation of active substances.

FURTHER REPORTS ON A SECOND CASE

About six months after publication of the report previously referred to,¹ I had the opportunity successfully to perform total gastrectomy in a second case.

From the Division of Surgery, the Mayo Clinic.
1. Walters, Waltman. Physiologic and Chemical Studies Following Total Gastrectomy for Carcinoma. J. A. M. A. 95: 102-106 (July 12) 1930.

Some clinical and surgical aspects of this case have been published from time to time² and these aspects will be subordinated here

A man, aged 69, who registered at the clinic, Dec 26, 1930, had had good health until eighteen months previously, when two attacks of generalized abdominal distress had occurred. A considerable quantity of bloody vomitus had accompanied the second seizure. His condition then had improved, and he had resumed his work. Two weeks before he returned to the clinic the distress had recurred after a large meal. Rigid dietary restriction had followed. Mild gaseous dyspepsia had been associated with the distress. Since the onset he had lost 9 pounds (4 Kg).

The patient was undernourished, had slight edema of the ankles and showed marked arteriosclerosis. Erythrocytes numbered 4,070,000 in each cubic millimeter of blood, the quantity of hemoglobin in each 100 cc. of blood was 86 Gm. Analysis of the gastric content revealed fresh blood clots and absence of free hydrochloric acid. Roentgenologic examination disclosed a large polypoid tumor on the posterior wall, in the upper half of the stomach, indistinguishable from a large malignant polyp. December 30, total gastrectomy was done with esophageal-jejunal anastomosis, posterior to the transverse colon, and a number 16 catheter was inserted temporarily in the distal part of the jejunum for the purpose of feeding. This jejunostomy tube was removed thirty-eight days following operation. The entire stomach (approximately 29 cm. in length) was removed. The growth proved to be an adenocarcinoma, graded 4, 15 by 10 by 3 cm. in various diameters without lymphatic involvement. Convalescence was uneventful.

TABLE 1—Results of Examination of the Blood

	12/26/30	3/16/31	3/18/31*	7/14/31	12/7/32†
Hemoglobin	86 Gm. in each 100 cc	54%		9.8 Gm in each 100 cc	9.6 (57%) Gm in each 100 cc
Erythrocytes per c mm	4 070 000	4 070 000	4 430 000	4 340 000	3 840 000
Leukocytes per c mm	9 400	3 700	4 200 or 4 900	5 100	3 900

Basophilic stippling					Positive
Basophils per cent			0.5		1.0

* Slight monocytosis moderate deficiency of hemoglobin good regeneration of erythrocytes
† Bleeding time one and a half minutes good regeneration of erythrocytes some mild hypochromasia

I have had an opportunity to reexamine the patient four different times in the last two years in December, 1930 in March and July, 1931 and, most recently, Dec 7, 1932 at which time he returned for study at my request. He was

found to be in excellent condition, with no evidence of recurrence of the carcinoma in any part of the body. Roentgenologic examinations were made of the esophageal-jejunal anastomosis, which was found to be normal and in roentgenologic appearance similar to what it had been on two other occasions subsequent to operation. The patient stated that he felt quite well and was definitely better than at any time since his operation two years previously, or even before that. He had gained 6 pounds (2.7 Kg) in the last two months, his appetite was

* 500 cc of water by mouth at 8 a m. Drank water in five minutes

fairly good, he sometimes felt "full in the stomach" shortly after beginning a meal, but this passed off and he was able to continue his meal, the bowels moved fairly regularly and there was no abdominal pain.

He was 71 at the time of this most recent examination. The blood pressure in millimeters of mercury was 132 systolic and 70 diastolic, with a pulse rate of 60 beats each minute. There were no masses to be felt in the abdomen, and on rectal examination the rectal shelf was found to be free from nodules.

Throughout this period of observation of two years, certain special studies have been carried out and a few complications have arisen. These will now be considered.

Studies of the Blood—Results of these investigations are recorded for the most part in table 1.

In July, 1931, chemical studies of the blood disclosed a concentration of urea of 40 mg in each 100 cc. The carbon dioxide combining power varied from 43 to 52 volumes per cent and the blood chlorides were 611 mg in each 100 cc.

Acidity of the Urine and the Alkaline Tide—In commenting on the physiologic effect of loss of the entire stomach in my earlier paper,¹ the study of the acid-base equilibrium in such a case, as evidenced by the presence or absence of an alkaline tide, seemed worthy of consideration. This was due to the fact that with the absence of the stomach and the loss of the acid and chloride secreting properties of gastric glands the question arose as to whether this might not produce a disturbance of the acid-base equilibrium. A study of that case by Dr Keith failed to show definite evidence of alkaline tide. In commenting on this, he stated that this observation was of interest, since it has been recognized that with the secretion of gastric juices in a normal person the urine tends to become more alkaline. The data up to that time (four months after operation) in that case appeared to indicate that the lack of a stomach and its acid secreting glands has a definite effect on the morning alkaline tide.

In the case reported in detail in this paper, Dr Keith has made similar studies, the results of which are presented in table 2. In commenting on the determinations made respectively on March 20, 1931, and Dec. 8, 1932, he noted that there was more marked diuresis on the latter date and that the urine was definitely diluted. There was a suggestion of an alkaline tide in the specimen passed from 8 to 9 a m, but none in the subsequent three specimens. There was no significant change in the excretion of chloride. The only definite change from the examinations on March 20 was a marked output of water,

with dilution. In commenting further, Dr Keith stated that the patient is getting along very well without a morning alkaline tide.

Röntgenologic Studies—March 16 and July 14, 1931, roentgen examinations of the thorax gave negative results. March 16, 1931 and Dec 7, 1932, roentgenograms of the stomach gave evidence that the esophageal-jejunal anastomosis was free and without deformity. The preoperative roentgenograms as well as the roentgenogram of the anastomosis made Feb 7, 1931, have been published previously,³ the present roentgenogram of the anastomosis is similar to the one published.

Complications—March 16, 1931, three months subsequent to operation, the patient returned for reexamination because of a soft mass measuring 6 by 4 cm., above the inguinal ligament on the right side. This mass had been noticed at the patient's dismissal immediately following operation, but the mass apparently had not changed in size. In March, what seemed to be enlarged inguinal nodes were noticed, several of them were removed for microscopic examination, but the changes in them were reported to be inflammatory only. The patient returned, July 14, 1931, and stated that the mass in the right lower quadrant had increased in size and that there was soreness in it at times. He stated that he had not been feeling as well as he formerly had. It was thought advisable to explore the fluctuating mass, which I did, July 16, 1931, through a right McBurney incision. Extraperitoneal drainage was instituted, opening into a cystic mass which contained about 700 to 800 cc of yellowish, milky fluid, without odor. Further exploration was not made, and there appeared to be no gross characteristics of a malignant lesion. A slight amount of similar material continued to drain from this region until October 8, when the patient returned for reexamination. At that time the abdominal sinus was opened and its interior explored with the finger. Nothing abnormal was found. The cavity was curetted, and a strip of iodoform gauze was placed within it. This gauze was removed a few days later and subsequently the sinus healed completely. There has been no further evidence of disturbance in this region. The etiologic factor concerned in the formation of this cystic mass is unknown. Whether it might have been leakage of the milk introduced through the jejunostomy tube during the thirty-eight days subsequent to operation is a matter of speculation. Against such an opinion is the fact that in the three months subsequent to operation the mass had not appreciably increased in size, but in the succeeding four months noticeable enlargement had occurred. The material, however, had the exact appearance of milky fluid.

SUMMARY AND CONCLUSIONS

Physiologic and chemical studies have been made on repeated occasions over a period of two years on the patient whose case is here reported in detail and on whom successful total gastrectomy was performed for an extensive, highly malignant carcinoma. This patient was living and well at the time this paper was written, with no evidences of recurrence or metastasis of the malignant lesion. Physiologic and chemical studies in this case, as well as in another case in which operation was successfully performed, and the patient studied over a period of eight months subsequent to operation, would indicate that in both cases but little change took place in the blood picture from that prior to operation. This applies to the percentage of hemoglobin as well as to the number and morphologic characteristics of the erythrocytes and leukocytes.

As one of the means of determining the effect of the loss of the acid and chloride normally secreted by the stomach, and absent as the result of the total gastrectomy, a study of alkaline tide would seem to indicate that such an alkaline tide was lacking in both cases. There was no change, however, in the excretion of chloride in the urine.

Roentgen studies of the esophageal-jejunal anastomosis revealed no evidence of recurrence over a period of two years in the case reported in detail in this paper and attention is called to an unusual and inexplicable complication, namely, the accumulation of milky fluid in the lower part of the abdomen just above the inguinal ligament, which necessitated incision and drainage seven months subsequent to operation. During the seventeen months subsequent to that time, there was no further evidence of complications.

HEREDITARY DIABETES INSIPIDUS

WILLIAM CHESTER, M.D.

AND

LOUIS SPIEGEL, M.D.

NEW YORK

Diabetes insipidus, which was differentiated from diabetes mellitus in 1674 by Thomas Willis, may be defined as a chronic disease characterized by marked thirst and the excretion of large quantities of a pale urine of low specific gravity.

Diabetes insipidus is classified into two types (1) secondary or symptomatic and (2) primary or idiopathic, including the hereditary instances.

Weils³ concerning 119 members of a family, 35 of which had diabetes insipidus, are noteworthy.

In several instances of diabetes insipidus in a family under our observation, therapy yielded very gratifying results.

REPORT OF CASES

CASE 1—History—A M., a married woman, aged 33 was born in Vermont and has lived in New York City since 1924.

Her father was known to have had diabetes insipidus, he died of pneumonia at the age of 41. Her mother is 55 years of age, living and well. The patient's paternal grandmother, maternal grandmother and a maternal aunt had diabetes insipidus.

The patient had minor childhood illnesses and has had frequent infections of the upper respiratory tract as an adult. There is a tendency to constipation and temperamental lability. She was operated on for appendicitis in May, 1931. Her menstruation is uneventful.

One child of the patient's first marriage and one of the second have diabetes insipidus. Her fluid intake and output increased approximately twofold during her three pregnancies and reverted to the previous level after parturition. The patient has never had sexual intercourse more frequently than two or three times a month.

Nocturnal and diurnal polyuria, polydipsia and pollakiuria have been present ever since the patient can remember, the fluid intake and output ranging from 8 to 16 liters in twenty-four hours. She feels more comfortable in the winter than in the summer months and has observed that her symptoms were not as marked when she lived in Vermont. She perspires little, even after exertion.

Examination—Save for the presence of small, well circumscribed lipid infiltrations (xanthelasma) at the inner canthus of both lower lids, the physical examination is negative.

The Wassermann reaction of the blood, Jan. 27, 1932, was negative. Chemical analysis of the blood showed sugar, urea nitrogen, uric acid, cholesterol total fats, calcium, phosphorus, chlorides, and total proteins all normal. The sugar tolerance test, January 29, after 50 Gm. of dextrose in 250 cc of black coffee was normal. A blood count revealed no abnormalities. Basal metabolism was normal.

Repeated urine examinations showed a low specific gravity, ranging from 1.003 to 1.006, neutral reaction, and numerous epithelial cells. Albumin and dextrose were absent.

A roentgenogram of the skull was negative. Because hospitalization was impossible, the patient was taught to measure her total fluid intake and output. After a satisfactory control period, trial doses of solution of pituitary were administered. It was found that from 15 to 2 cc of solution of pituitary divided into two doses administered in the morning and before retiring, diminished the fluid intake and output from 12 to 3 or 4 liters and enabled the patient to go through the night without drinking or voiding. Solution of pituitary by nasal spray (0.5 cc. three times a day, the last dose shortly before retiring) was then substituted for the hypodermic injections. The results were equally gratifying. On several occasions when the supply of the drug was exhausted the excessive thirst and polyuria returned, the total fluid intake and output being approximately that prior to the institution of the treatment with solution of pituitary. The patient was advised to increase the evening dose if she had indulged in a very heavy supper, to avoid nocturia. In addition there was a marked decrease in irritability. The patient was under our observation from January to June 1932, the diabetes insipidus syndrome being controlled with nasal sprays of solution of pituitary.

CASE 2—Alfred M., the oldest child aged 14, weighed 11 pounds (5 kg) at birth and was delivered instrumentally. He was breast fed for eight months and he talked and walked between 1 and 2 years of age. In early childhood he had uncomplicated measles and whooping cough. Polyuria, polydipsia, pollakiuria and nocturnal enuresis were first noted at

the age of 5 years. His fluid intake and output averages from 12 to 15 liters in twenty-four hours, the nocturnal polyuria and polydipsia ranging from 3 to 5 liters. The child lives in Vermont with his grandparents, and we have not, as yet, been able to examine him.

CASE 3—History—Fredrick M., aged 7 years, weighed 7 pounds (3.2 Kg) at birth and was delivered instrumentally. He was breast fed for two months and then weaned because of unaccountable irritability and apparent dissatisfaction with the mother's milk. For the past two years the child has had nocturnal and diurnal polydipsia, and enuresis, the latter of late being nocturnal only.

Examination—Physical examination was negative.

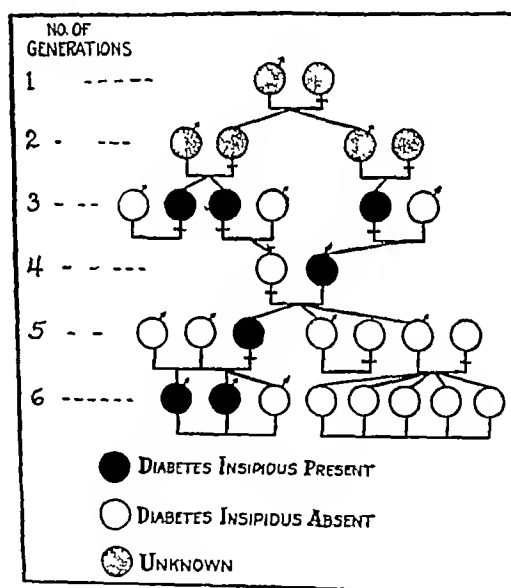

Laboratory Data—Chemical analysis of the blood, Feb 17, 1932, showed the sugar, urea nitrogen, cholesterol, chloride and calcium all normal. The urine was normal save for low specific gravity, 1.002 to 1.006.

A roentgenogram of the skull showed slight exaggeration of the normal digital markings. The sella turcica was normal. There was cloudiness of both antrums.

Pituitary therapy (0.5 cc of solution of pituitary) administered by nasal spray before retiring diminished the threshold of water exchange and eliminated enuresis.

COMMENT

Secondary or symptomatic diabetes insipidus may be associated with pathologic anatomic lesions at the base of the brain involving the pituitary gland, the struc-

Geneological table of our patients with hereditary diabetes insipidus. The cases described in the text are of the fifth and sixth generations.

tures of the midbrain or, more rarely, both. Hypophyseal lesions are most frequent, the processes occasionally extending beyond the confines of the posterior lobe to the so-called pars intermedia and even to the anterior lobe.⁴ The exact location of the lesion in experimentally produced diabetes insipidus is still a question. However, it is generally believed that the causative factor of diabetes insipidus is a disturbance in the pituitary-midbrain system (neurohypophysis, infundibulum, tuber cinereum and mamillary bodies).

The etiology of primary or idiopathic diabetes insipidus is unknown. Necropsy reports in the hereditary type are unusually rare. Marinesco² mentions proliferation of the lining epithelium of the fourth ventricle with the formation of cellular excrescences. His patient however, died of tuberculous meningitis, which may well account for the pathologic manifestations.

present One of our cases, as well as an instance described* by Fitcher,⁵ presented lipoid infiltrations of the eyelids (xanthelasma) One of us,⁶ in a previous communication, pointed out that these deposits may simply be a beauty defect, but at times they are objective signs of a severe disturbance in lipoid metabolism (lipoidgranulomatosis) in which one of the clinical pictures (type Hand-Schüller-Christian) has as one of its cardinal symptoms the diabetes insipidus syndrome

Hereditary diabetes insipidus is most frequently detected in infancy or early childhood Longevity is common in those surviving infancy, three of Weil's patients living to the age of 83, 87 and 92 years

Hereditary diabetes insipidus is somewhat more common in males than in females

Race and climate have no effect on its occurrence

Consanguinity (intermarriage of cousins) was present in Weil's cases and in our own

Hereditary diabetes insipidus may be transmitted through the maternal or paternal side to either male or female children Sometimes one generation may be skipped (Wachsmuth, Reith, Clay, McIlraith) We are unable to agree with Liebmann,⁷ who believes that the transmission is similar to that of hemophilia Analysis of the instances of hereditary diabetes insipidus (Pain, Weil and Knopfmacher) supports our contention

SYMPTOMATOLOGY

In order to appreciate the symptomatology of hereditary diabetes insipidus, particularly the differences in infants and adults, it is necessary to consider the rôle of the kidneys in the regulation of water balance This has been extensively studied by Veil⁸ whose monograph on the subject appeared recently

According to Veil, the kidneys in infants play a comparatively minor rôle in the regulation of water exchange, the important factors being the skin and the gastro-intestinal tract From 17 to 56 per cent of the water is eliminated through the skin of the infant in the form of insensible perspiration, including sweat In older children, this is decreased to from 15 to 32 per cent To their function of excretion of metabolic wastes, at about 2 years of age the kidneys add the function of regulation of water balance In addition, at this age, the nervous enervation of the bladder and kidneys has developed, as evidenced by attempts at voluntary control of the bladder It is thus quite evident that the symptomatology in infancy and adult life varies considerably
